GENERAL INTRODUCTION

In 1976, almost 50 percent of the total beef production was consumed as ground beef. This amounted to approximately 11 billion pounds. It is estimated that by 1980 this figure will exceed to 55 percent. Beef generated from cattle-fed grain supplied approximately 3 billion of the 10 billion pounds of ground beef derived from forage-fed beef. This forage-fed beef was predominately from USDA Utility or lower grade carcasses or from imported cow beef. (USDA and military specifications require a minimum quality grade of U.S. Utility on beef used for ground beef. In 1976, Cross et al., reported that ground beef prepared from U.S. Utility or lower grade beef was unacceptable in tenderness. This lack of tenderness was primarily due to the amount of connective tissue in the product. It appears that some system should be devised so that a major portion of the connective tissue could be removed prior to formulation into a final product. This would ensure a product more acceptable in texture. Cross et al. (1977) investigated the effect of grinding plate size on textural properties of ground beef. Their results indicate that grinding method has a significant effect on tenderness and amount of connective tissue. The larger the initial plate size, the tougher the meat and the more connective tissue detected by the panel. Previous research in this laboratory (Cross et al. 1977) indicated that beef ground in the conventional manner (3/4 x 1/8 inch) yielded more detectable connective tissue than ground beef prepared with other methods of comminution.

Sensory panels found patties from U.S. Utility or lower beef to be unacceptably tough. Cross et al. (1978) investigated a new process called "desinewing" that removes most of the objectionable connective tissue during production of ground beef. These workers found that desinewing greatly improved the textural properties of beef patties produced from mature beef animals.

Since ground beef represents a sizeable portion of the meat dollar, it merits more research attention than it has been given. Little or no published data is available in the following areas:

1. The most suitable method of comminution for a particular grade or cut of meat;
2. The effect of temperature of raw material on product quality;
3. The effect of type and amount of fat on product quality;
4. The most suitable cooking method and patty size.

The Meat Science Research Laboratory has designed studies to answer these questions. The projects were divided into eight phases to be conducted over a period of two years. USDA contracted to complete three phases (I, II, and VI) with the U.S. Army Natick Research and Development Command. This final report will present the results by phase.

PROJECT PERSONNEL

Dr. H. Russell Cross, Research Food Technologist

Dr. Brad W. Berry, Research Food Technologist

Dr. A. W. Kotula, Research Food Technologist

Ms. Linda Wells (Graduate Assistant)

Dr. Bonnie Emswiler, Research Microbiologist

Ms. Ivonne Terment, Food Technologist

Ms. Judy Quick, Biological Laboratory Technician

Ms. Marilyn Stanfield, Biological Laboratory Technician

Mr. Dave Muse, Statistician

OVERALL SUMMARY & CONCLUSIONS

DESINewing

1. Desinewing with the 0.19 cm - 0.25 cm stepped head reduced the Instron shear force, while improving sensory panel scores for all palatability traits when compared to grinding.
2. All four desinewing methods reduced the amount of soluble, insoluble and total collagen in raw patties when compared to grinding.
3. Data generated from this study indicates that desinewing results in a more acceptable product when compared to grinding.
4. Desinewing with the 0.19 cm head or the 0.19 - 0.25 cm stepped head improved the quality of chilled Cutter-Canner cow when compared to ground chilled Cutter-Canner beef. On the other hand, the palatability of hot Cutter-Canner cow beef patties was not improved by desinewing.
5. Desinewing of mature bull and Cutter-Canner cow meat produced a product of high quality (equal to Choice trimmings). Similar results were obtained when the lean was ground hot (unchilled).

HOT GROUND BEEF

6. Ground beef patties prepared from hot processed beef were more tender and juicy than patties prepared from chilled beef.
7. Total cooking loss was significantly less in the hot processed patties when compared to the chilled patties.
8. Hot processed patties had less configuration changes than chilled patties.
9. Ground beef prepared from hot-boned carcasses has bacteriological quality and shelf-life that are equal to or better than those of ground beef prepared from chilled carcasses.

FROZEN LEAN SOURCE

10. Frozen lean source had few practical effects on palatability or cooking properties.

PATTY SIZE

11. Patty size had significant effects on tenderness, juiciness, amount of detectable connective tissue, and flavor intensity. The 3.6 oz patties received significantly lower ratings in all of the aforementioned palatability traits when compared to the 4.0 and 8.0 oz patties.

PATTY TREATMENT

12. Patty treatment (knife, waffle, or plain) did not enhance any palatability trait. Untreated patties (plain) were more tender and juicy than patties receiving the knife or waffle treatment.
13. There appears to be no advantage (other than appearance) to subjecting the surface of the patty to a knife or waffle treatment. This data indicates that these treatments may actually have negative effects on palatability.

GRINDING VS FLAKING

14. Neither method of processing (grind vs flake) nor state of product when cooked for evaluation (precooked vs frozen-raw) exerted a practical effect on palatability, Instron values, or cooking characteristics in this study.

GRINDING VS CHOPPING

15. Generally, grinding, chopping or a combination of grinding and chopping as the initial particle reduction system did not greatly affect palatability, physical or chemical values.
16. There was some tendency for chopping to yield slightly higher tenderness scores and less detectable connective tissue than grinding.

FAT SOURCE & FAT LEVEL

17. As the percent fat increased from 16 to 30%, tenderness and juiciness scores increased.
18. Total cooking losses were not affected by fat level.
19. Type of fat did not affect the quality of ground beef.

STORAGE

20. The 9 months storage of ground beef patties containing 16, 20, 24, or 30% fat resulted in an increased incidence of off flavors and reduced tenderness and juiciness scores. The effects of various fat levels noted at 0 months remained about the same at all successive time intervals.
21. Source of fat had no significant affects on storage properties.

SHELF-LIFE

22. Storage time appeared to exert more influence on shelf-life than source of product or level of fat. However, formulations containing kidney and brisket fat had higher bacterial counts when formulated to 24% fat and were darker in color at the completion of the shelf-life study.
23. Higher incidences of off-odor were associated with higher levels of fat in the product.

PHASE I - PART 1

Objective: To determine the most suitable method of mechanical desinewing hot and chilled mature cow and bull beef for use in beef patties.

CHARACTERISTICS OF BEEF PATTIES AS INFLUENCED BY
MECHANICAL DESINewing CLASS OF BEEF
TRIMMINGS AND HOT VS COLD BONING

Introduction

The consumption of ground beef has steadily increased over the past few years. It has been estimated that by 1980, 50% of the beef consumed in the U.S. will be consumed as ground beef. Cross et al. (1978b) reported that connective tissue was a major problem associated with the acceptance of ground beef. Patties formulated from Prime, Choice, and Good grade carcasses were rated as acceptable for the palatability traits of tenderness, connective tissue amount, and overall acceptability by a sensory evaluation panel (5.0 or above on a 9 point scale). On the other hand, patties from Utility and Cutter grades were rated as unacceptable in quality, (4.0 or less on 9 point scale). Since the major source of lean in ground beef is derived from mature animals, it would be desirable to improve the acceptability by removing the connective tissue. Some purchase specifications for ground beef do not presently permit the use of mature cow and bull beef in the formulations. A new technique has been developed whereby the connective tissue or sinew is removed. This technique is referred to as "mechanical desinewing." The objective of this study was to evaluate the effect of mechanical desinewing versus grinding on mature bull and cutter-canner cow beef, plus choice trimmings.

EXPERIMENTAL

Sixteen formulations of ground beef were manufactured by grinding or desinewing USDA Cutter-Canner cow chucks, mature bull chucks, Choice plates, and Choice trimmings. The raw materials were purchased at a local commercial packing plant and trucked to the Beehive Machinery laboratory at Sandy, Utah. Each raw material was ground through a 5.1 cm breaking plate. A random sample of 6.8 kg was taken during the 2 inch break and finely chopped for fat analysis by the Modified Babcock procedure. Fat content was standardized at 24% fat for desinewed treatments. Previous research by Cross et al. (1978) determined that desinewing removes 2-3% of the fat (Table 1).

GRINDING

Treatments were formulated to 22.7 kg by mixing the appropriate amount of lean and fat source for 3 min. CO₂ was added during the 3 min mix to reduce the temperature to 2-3 C. Following mixing treatments were either ground through a 0.32 cm plate or desinewed through either a 0.19 cm head, 0.25 cm head, 0.19 - 0.25 stepped head, or a 0.25 cm - 0.32 cm stepped head. All treatments were then formed into 145 g patties on a Hollymatic patty machine, placed in a box and frozen at -26 C. Within 2 weeks the boxed frozen patties were packed in dry ice and shipped via air freight to Beltsville, Md. Upon arrival, patties were wrapped in butcher paper, 3 patties per package, boxed and stored at -25° F.

COOKING PROCEDURES

Frozen patties were weighed, the diameter and height recorded, then broiled for 8 min on one side turned and broiled for 6 more min on the other side using electric Farberware grills (Model 450). Immediately following

broiling, patties were removed from the grill, temperature measured with a thermocouple, re-weighed, diameter and height re-measured to determine % cooking loss, % diameter change and % height change. Patties for sensory panel evaluation were sliced into eights and two slices were served hot to each panelist. Patties to be used for Instron Universal Shear were quartered, cooled to room temperature and then sheared to determine total work and peak shear force. Degree of doneness was evaluated by comparison with color photographs immediately after slicing.

CHEMICAL PROCEDURES

Ten patties per treatment were thawed until pliable and then passed through a 0.32 cm plate followed by a 0.24 cm plate. Triplicate samples were taken to determine the % fat and % moisture raw according to the AOAC approved procedure. Ten patties per treatment were cooked and subjected to the above mentioned technique to determine % fat cooked and % moisture cooked. Chemical connective tissue amount was determined according to the hydroxyproline procedure of Hill (1966) employing the color step of Bergman and Loxley (1963). Rancidity was determined by calculating the TBA number using the extraction procedure of Tarladgis et al. (1964). For the above mentioned chemical procedures, ten patties were powdered and duplicate samples per treatment were analyzed.

PANEL SELECTION AND TRAINING

An eight-member panel was selected and trained in descriptive attributes by the procedures of Cross et al. (1978). The panel rated the following attributes using an eight-point structured scale: a) initial and final tenderness, 8 = extremely tender and 1 = extremely tough; b) juiciness, 8 = extremely juicy and 1 = extremely dry; c) initial and final connective tissue

amount, 8 = none and 1 = abundant; d) ground beef flavor intensity, 8 = extremely intense and 1 = bland. Panelists rated four to six treatments at each of 24 sessions.

STATISTICAL ANALYSIS

Specific linear comparisons were made on each parameter evaluated to determine the effect of method of comminution and lean source on ground beef quality. The study was divided into three parts, (Table 2) each part will be discussed separately.

RESULTS & DISCUSSION

PART A: Four linear comparisons were made. Comparison 1 tested the effect of desinewing with the 0.19 cm head versus desinewing with the 0.25 cm head; Comparison 2 tested the effect of desinewing with the 0.19-0.25 cm head versus desinewing with the 0.25-0.32 cm head; Comparison 3 tested the effect of single aperture size versus double aperture size; and Comparison 4 tested the effect of grinding 0.32 cm versus desinewing. The effect of source along with the interaction of source with comparison was also tested.

Desinewed cutter-canner cow chucks were rated higher by sensory taste panel for initial and final tenderness when compared to grinding. Bull chucks on the other hand received slightly higher scores for initial tenderness when desinewed, but received lower scores for final tenderness when desinewed. Total shear work decreased for cutter-canner cow, while bull meat increased when desinewed (Figure 1). Among desinewing methods, the 0.19 cm head and 0.19-0.25 cm head produced higher initial and final and final tenderness scores for all raw materials when compared to other desinewing heads (Table 3). This result can be seen in Figure 2a, b where total shear work and shear force was less for bull and cow meat desinewed with the 0.19 cm head. The use of a double or stepped head reduced the shear force and total work to shear for bull meat when compared to a single head. The reverse was true for cutter-canner cow (Figure 2). The 0.19-0.25 cm stepped head significantly reduced total shear work and shear force ($P < .01$). However, grinding with the 0.32 cm plate significantly decreased shear force ($P < .01$) when compared to desinewing (Table 3). Sensory panel scores for juiciness were significantly higher ($P < .01$) for desinewing vs

grinding, with the 0.19 cm head higher than the 0.25 cm head. Removal of connective tissue would concentrate the lean tissue containing moisture. Ground beef flavor intensity followed the same pattern as juiciness (Table 3). The amount of detectable initial and final connective tissue amount decreased when desinewed for cutter-canner cow, however the opposite was true for bull meat (Figure 3a, b). Comparison 1 revealed that desinewing with the 0.19 cm head reduced the detectable connective tissue amount when compared with the 0.25 cm inch head (Figure 3 c, d). Desinewing with the 0.19-0.25 cm stepped head resulted in higher scores for initial and final connective tissue amount versus the 0.25-0.32 cm stepped head. Chemical determination of connective tissue, by hydroxyproline procedure produced similar results as was detected by sensory panel scores. The amount of insoluble and total collagen (mg/g) was reduced by desinewing with the 0.19 cm head compared to the 0.25 cm head. Insoluble collagen was less when the 0.19-0.25 cm head was used versus the 0.25-0.32 head (Figure 4b, c, d). While the sensory panel detected more final and initial connective tissue in desinewed versus ground bull meat, chemical determinations showed less connective tissue in desinewed meat. Cutter-canner cow had less chemically determined connective tissue and higher sensory scores when desinewed (Figure 5a, b). Desinewing with single aperture heads reduced the amount of insoluble and total collagen for both raw material (Table 5). Conversely, soluble collagen was higher when the single aperture head was used for bull meat compared to the stepped heads (Figure 4a).

The % change in height was more for patties produced from the 0.19 cm head versus 0.25 cm head. Likewise, patties from the 0.19-0.25 cm head underwent more height change (%) than patties from the 0.25-0.32 head regardless of whether the product was from bull or cow meat (Table 7).

Grinding bull meat decreased the % height change in contrast to desinewing while the opposite was true for cow meat (Figure 5c).

The % diameter change for cow meat was less when a stepped head was used vs a single head (Comparison 3), but the reverse was true for bull meat (Figure 5d). % Cooking loss was only significant for Comparison 1 ($P < .01$) with the 0.19 cm head resulting in more cooking loss than patties from the 0.25 cm head.

The % moisture of cooked patties was significantly more ($P < .01$) for for desinewed versus ground meat (Table 7). Within the four desinewing heads, use of stepped heads reduced the % moisture in bull meat. Among the two stepped heads, use of the 0.19-0.25 cm versus 0.25-0.32 cm increased the % moisture in cow meat. The single aperture 0.19 head (Comparison 1) reduced the % moisture for both sources of meat (Figure 6a, b, c).

CONCLUSIONS

In general, desinewing with the 0.19 cm or 0.19-0.25 cm stepped head reduced instron shear work and force, while improving sensory panel scores for all palatability traits when compared to grinding. Desinewing with the 0.100 inch head generally resulted in the least moisture loss, diameter change, height change and cooking loss. All four desinewing methods reduced the amount of soluble, insoluble, and total collagen in raw patties when compared to grinding. In general, bull meat yielded higher sensory scores for tenderness and connective tissue, less insoluble and total collagen, plus less total shear work and force. The data generated from this study generally indicates that desinewing with the 0.19 or 0.19-0.25 cm stepped head results in a more acceptable product when compared to grinding. Bull meat was preferred by the sensory panel to cutter-canner cow meat.

RESULTS AND DISCUSSION

PART B: The effect of hot versus chilled cutter-canner cow was tested with the same four linear comparisons as Part A. Comparison 1 = 0.19 cm head vs. 0.25 cm head; comparison 2 = 0.19-0.25 cm stepped head vs. 0.25-0.32 cm stepped head; comparison 3 = single aperture size vs. double aperture size; and comparison 4 = grind 0.32 cm vs. all desinew. The source of lean by method of comminution interaction was also tested.

Sensory panel scores for tenderness increased and Instron total work decreased when chilled cutter-canner cow was desinewed, as compared to grinding. However, the opposite was true for desinewed vs. ground hot cutter-canner cow beef (Figure 7a, b). Desinewed hot and chilled cutter-canner cow beef patties required significantly ($P < .01$) more force to shear when compared to ground beef (Table 9). Instron shear (^2Kg) increased for both chilled and hot cow meat when a stepped head vs. a single aperture head was used (Figure 7d). Initial and final tenderness was improved significantly ($P < .01$) when desinewed with the .19 cm head compared to the .25 cm head (Table 9). This is verified by Instron total work and shear force which decreased with the smaller aperture size (Figure 8c, d). Comparison 2, within stepped heads, revealed higher sensory scores for final tenderness when the 0.19-0.25 cm head was used regardless of the temperature of the beef (Table 9). Chilled and hot meat responded differently when desinewed with the 0.19-0.25 vs. 0.25-0.32 for Instron total work and shear force. Total work and shear force decreased for chilled cow as aperture size decreased, however total work and shear force increased for hot cow patties as aperture size decreased (Figure 8a, b).

Initial connective tissue amount, as detected by sensory panel, decreased when chilled cow meat was desinewed. Higher sensory scores reflect less detectable connective tissue. Conversely, the sensory panel detected more initial connective tissue (lower scores) when hot cow beef was desinewed (Figure 9a). Chemical determination of soluble, insoluble, and total collagen decreased for both hot and chilled cow meat when desinewed compared to ground (Figure 10a; b and Table 9). Initial and final connective tissue scores increased to a larger magnitude for hot meat compared to chilled when desinewed with the 0.19 cm head vs. the 0.25 cm head (Figure 9b, c). In addition, total and insoluble collagen was reduced by a larger magnitude when cow beef was desinewed with the 0.19 cm vs. 0.25 cm (Figure 10c, d). Soluble collagen was also less for beef desinewed with the 0.19 cm head vs. 0.25 cm head (Table 9). In this case, subjective sensory scores and objective chemical determination of connective tissue for comparison 1 paralleled each other. Final connective tissue scores were lower for hot cow meat desinewed with the 0.19-0.25 cm stepped head compared to the 0.25-0.32 cm stepped head. The reverse was true for chilled cow beef patties (Table 9). Generally, the amount of chemically determined insoluble and total collagen increased when chilled cow was desinewed with stepped vs. single aperture size heads. Conversely, when hot cow was desinewed with a stepped head, total and insoluble collagen decreased (Figure 11a, b). Juiciness scores increased when chilled cow meat was desinewed vs. ground, but scores for hot cow meat decreased for this comparison (Figure 12c). Within single aperture size heads, 0.25 cm desinewed hot cow beef product received higher scores than 0.19 cm desinewed hot cow beef. On the other hand 0.19 cm desinewed chilled cow beef received higher scores than 0.25 cm desinewed chilled cow patties (Table 9). Ground beef flavor intensity decreased for desinewed hot cow samples, but increased for desinewed chilled cow when compared to ground beef patties

(Figure 12d). The percent moisture in cooked samples decreased substantially when hot cow beef was desinewed with a double aperture stepped head compared to single aperture heads, while chilled cow changed very little in moisture attributable to desinewing method (Figure 12a). Within single aperture heads, 0.19 cm desinewed chilled cow beef patties decreased in percent moisture to a large degree while hot cow changed very little (Figure 11c). Within stepped heads, both hot and chilled cow beef patties increased in percent moisture cooked when desinewed with the 0.19-0.25 cm head (Figure 11d). The percent cooking loss decreased when chilled cow was desinewed with stepped heads vs. single aperture heads, but hot cow increased in percent cooking loss when desinewed with stepped heads vs. single aperture heads. Additionally, the percent cooking loss increased when desinewed with the 0.19 cm in head, vs. the 0.25 cm head (Table 9). The change in diameter of patties in cooking increased when hot and chilled meat were desinewed with the 0.19-0.25 cm head vs. the 0.25-0.32 cm in head (Table 9).

CONCLUSIONS

In general hot ground or 0.19 cm desinewed beef patties were, (1) rated higher by sensory panel for all palatability traits except flavor intensity; (2) received lower Instron total work and shear force readings; and (3) had less soluble, insoluble and total collagen than patties from chilled beef. Hot and cold boned cutter-canner cow when desinewed had less soluble, insoluble, and total collagen when compared to ground treatments. However, sensory panel scores for connective tissue amount did not reflect the removal of collagen by desinewing. Overall, desinewing with the 0.19 cm head or the 0.19-0.25 cm head improved the quality of chilled cutter-canner cow when compared to ground chilled cutter-canner cow beef. On the other hand, the palatability of hot cutter-canner cow beef patties was not generally improved by desinewing.

RESULTS AND DISCUSSION

PART C: This part dealt with comparisons of desinewing with the 0.19cm head vs grinding with a 0.32 cm plate using mature bull, chilled Cutter-Canner, and Choice trimmings. Specific linear comparisons were designed to test the effect method of comminution, bull vs Cutter-Canner cow (Comparison 51) and the average of bull plus Cutter-Canner cow vs Choice trimmings (Comparison 52). The interaction of method of comminution by comparison was also tested.

The effect of method of comminution was significant ($P < .01$) for final tenderness. Final sensory panel tenderness scores were improved by desinewing bull and cow meat, but reduced slightly by desinewing choice trimmings (Table 14). Initial tenderness was significant ($P < .01$) for the interaction of comminution x Comparison 51. Improvements in initial tenderness scores attributable to desinewing were greater for Cutter-Canner cow beef than bull meat. Scores for final tenderness followed the same pattern (Figure 13b). Instron total work was reduced by desinewing compared to grinding for all raw materials (Table 16). Bull meat patties required significantly ($P < .01$) less total shear work than Cutter-Canner cow patties. In addition, patties from Choice trimmings required significantly ($P < .01$) less total work than the average of all mature beef patties. Maximum shear force followed the exact same pattern as total shear work (Table 13). Sensory panel scores for initial connective tissue were significantly higher ($P < .01$) for bull meat patties (reflecting less connective tissue) when compared to Cutter-Canner cow regardless of comminution method. This was verified by the objective measurement of chemically determined insoluble and total collagen. Bull meat had less insoluble and total collagen than Cutter-Canner cow patties when produced by either method of comminution (Table 13). Soluble collagen was removed

from Choice trimmings to a larger degree than mature beef (Figure 13c).

Insoluble and total collagen were also substantially removed from Choice trimmings when compared to the average of bull and cow. This was evidenced by the steeper slope of the line for Choice beef patties (Figure 13d, 14a). Juiciness and ground beef flavor intensity were significantly ($P < .01$) higher for desinewed, patties made with the 0.19 cm head, vs ground meat (Table 14). Higher percentages of cooking loss were found for patties from Choice trimmings than product made from mature beef (Figure 14b). Conversely, the percent moisture in cooked desinewed Choice product was higher than that of mature beef patties (Figure 14c). The percent moisture in cooked Cutter-Canner cow patties was significantly ($P < .01$) higher than mature bull samples (Table 13). The percent change in patty height increased substantially for mature bull meat when desinewed, whereas Cutter-Canner cow product changed very little between grinding and desinewing (Figure 14d). Choice trimmings had a larger percent height change than mature beef (Table 13).

CONCLUSIONS

In general Choice trimmings received higher scores for all palatability traits followed closely by the scores of bull meat product. Cutter-Canner cow samples received the lowest sensory panel scores. Desinewing tended to increase palatability scores for all traits when compared with grinding. Desinewing also tended to reduce the amount of soluble, insoluble, and total collagen, plus reduce total Instron shear work and force. On the other hand, mechanical desinewing increased cooking losses and dimensional changes when compared to grinding. In general, sensory panel scores for initial and final connective tissue amount, scores were similar for product from Choice trimmings

and mature bull meat, with scores for Cutter-Canner cow being lower (Table 14). Conversely, chemical collagen as determined by the hydroxyproline procedure of Hill (1966) was highest in Choice trimmings, followed by Cutter-Canner cow and mature bull products displaying the least amount of chemically determined collagen (Table 15). This situation exemplifies the problems associated with a trained sensory taste panel being able to detect connective tissue in ground beef.

In summary, the desinewing of mature bull and Cutter-Canner cow does create a product of higher quality from a sensory standpoint. The best selection of desinewing heads would be the 0.19cm followed by the stepped (0.19 - 0.25 cm) head. Hot Cutter-Canner cow beef also creates high palatability ratings when ground. Data from this study indicates that the palatability of hot Cutter-Canner cow patties is reduced by mechanical desinewing.

Phase I - Part 2

Objective: To evaluate the effect on palatability
and shelf-life of preparing ground
beef from unchilled (hot) beef carcasses.

PHYSICAL, CHEMICAL & SENSORY PROPERTIES OF GROUND BEEF

PREPARED FROM HOT AND CHILLED BEEF CARCASSES

Introduction

More than 40 million cattle and calves are being slaughtered in the U.S. each year. Vast amounts of energy are currently being used to process, transport and market this volume of meat. Alternate processing methods such as hot-boning offers tremendous possibilities in energy conservation and increased marketing efficiency. By the year 1980, about 50% of the beef slaughter will be consumed as ground beef (Pietraszek, 1975).

The ground beef industry represents a large proportion of the total energy requirements of the meat industry. Little, if any, data have been reported concerning the feasibility of producing ground beef from hot processed beef carcasses. Several potential problems of hot boning include textural changes, color differences and shelf-life. In order for the ground beef segment to be viable, the hot processing of steak and roast cuts from the same carcasses must also be possible. Much of the hot processing data in the literature have concentrated on the palatability of steaks and roasts from USDA Good and Choice carcasses (Kastner et al., 1973; Falk et al., 1975 and Schmidt and Gilbert, 1970). No data are reported on the effect of hot boning of mature (> 4 yrs) beef carcasses on shelf-life and palatability. The steak and roast cuts from these carcasses are usually tenderized by mechanical and enzymatic methods. This laboratory is currently investigating the effects of hot boning on the physical, chemical and microbial properties of ground

beef and steaks and roasts from mature beef carcasses. This manuscript will deal with the palatability and cookery yields of the ground beef segment of the study.

EXPERIMENTAL

Hot processed ground beef was prepared by three methods as outlined in Table 1. Each method contained two batches and each batch contained 4 sides of beef. Batch A was prepared in the a.m. and Batch B in the p.m. Opposite sides were assigned to the same batch for cold boning. Carcasses ranged in USDA quality grade from low to high utility and in maturity from "C" to "E" (> 4 yrs). The animals were slaughtered and the ground beef was prepared and stored at a commercial processing plant. One side of each carcass was hot-boned; the other half, cold-boned. At 3 hr postmortem, the top round, strip loin and ribeye cuts were removed from one side of each hot carcass and at 24 hr postmortem, the same muscles were removed from the sides which had been chilled at 2 to 3°C and set aside for a different study. The remainder of the meat from the boned carcasses was used for ground beef fabrication in this study.

GRINDING METHODS - Chilled (control)

U.S. Choice plates (conventionally chilled) were added (approximately 30%) to the formulation in order to bring the final fat content to $21 \pm 2\%$. The cow lean and choice plates were passed through a 1.27 cm plate, mechanically mixed for 3 min and ground through a 0.32 cm plate for the final grind. The average batch size was 360 to 400 kg. The control formulation was not actually a "control" because the grinding system was not identical

to those used for hot meat. The purpose of the experiment was to compare new systems that might work for hot meat with the most common system used for chilled meat.

METHOD 1 - Hot Processed

U.S. Choice plates (2 to 3°C) were added (approximately 30% of the formulation) to the formulation in order to bring the final fat content to $21 \pm 2\%$. The hot lean and chilled beef plates were passed through a large kidney plate (1.27cm x 1.90cm) and mixed for 3 to 4 min. During mixing, CO₂ snow was added at a 1:10 ratio of CO₂ to beef. Following the mix, the product was ground through a 0.32 cm plate for the final grind.

METHOD 2 - Hot Processed

Method 2 differed from method 1 only in the number of grinds and the manner in which the CO₂ snow was added. The lean and fat was passed through a kidney plate, mixed 3 to 4 min; passed through a 1.27 cm plate, mixed 3 to 4 min and passed through a 0.32 cm plate for the final grind. The CO₂ snow was added at a ratio of 1:10 with two-thirds added during the first and one-third during the second mix.

METHOD 3 - Hot Processed

Method 3 differed from method 2 only in the amount of CO₂ snow added and the absence of choice plates. Since no chilled choice plates were added the ratio of CO₂ snow to meat was increased to 1.5:10. Also the carcasses used for this method were slightly fatter than those used in methods 1 and 2 in order for the final fat content to be $21 \pm 2\%$.

PATTIES

Ground beef from all formulations were formed into 113 g (4 oz) patties using a FORMAX model 26 patty machine. Patties were stacked (10 per stack)

boxed and frozen in a blast freezer and stored at -10°C for 5 days before shipment to Beltsville, Md. for analysis.

TRAINED PANEL

A 10-member descriptive attribute panel, trained by the procedures of Cross et al. (1978a) and AMSA (1978), evaluated samples from each treatment in a total of 10 sessions. Six samples were evaluated per session and each treatment was replicated 5 times. The panel rated each sample for differences in tenderness, juiciness, connective tissue amount and ground beef flavor intensity with 8= extremely tender, juicy, no detectable connective tissue, and intense and 1= extremely tough, dry, abundant connective tissue and bland in ground beef flavor.

COOKERY AND PRESENTATION TO PANEL

Frozen patties were broiled on electric Farberware grills (model 450-A) to an approximate internal temperature of 60°C . Temperature was monitored during cooking with teflon-coated iron/constantan thermocouples. Beef patties prepared from hot-boned beef carcasses required 11 minutes total cooking time while the control patties required 13 min. Frozen and cooked weights were obtained in order to calculate total cooking losses. Four patties were prepared for each session. Each patty was sectioned into 6 pieces and two of the 24 pieces (4 patties) were randomly assigned to each panelist. The samples were served as warm as possible to the panelist as described in ASMA (1978). After sectioning, the pieces were pictorially scored for degree of doneness (color photographs with 1= well done and 8= rare) by a trained laboratory technician.

SHEAR FORCE

Ten patties from each method/batch group were used for determination of Instron shear force according to the single-blade procedure outlined by Cross

et al. (1978b). Four 2.54 cm squares were obtained from each patty, thus each mean value for method/batch represents 40 observations.

PHYSICAL AND CHEMICAL

Height and diameter measurements were obtained on the ten frozen and cooked patties used for the Instron. Percent fat and moisture was determined on raw and cooked patties according to AOAC procedures. A pH determination was made on ten frozen, thawed and cooked patties from each treatment using the procedure described by Nichols and Cross (1978).

RESULTS AND DISCUSSION

Data in Tables 2-4 combines methods of processing to allow a direct comparison of sensory, physical and chemical properties of ground beef prepared from hot versus chilled beef. Mean palatability and shear force values are presented in Table 2. Ground beef patties prepared from hot processed beef were significantly ($P < .05$) more tender (panel) and juicy than patties prepared from chilled beef. Differences in shear force were not evident although the trends were similar to those established by the trained panel. As might be expected, treatment had no significant effects on amount of connective tissue or flavor intensity.

Total cooking loss was significantly less in the hot processed patties when compared to the chilled patties (Table 3). The differences were quite large (33.85 vs 41.06%) and of considerable practical importance. These differences in cooking losses were reflected in ratings for juiciness (Table 2). Hot processed patties had significantly less configuration change and diameter than chilled patties. Percent change in height and thaw loss was not significantly affected by treatment. In an institutional-use situation,

the most important configuration parameter would be diameter in order to keep a constant area of the bun covered.

Since the hot-boned beef was processed prerigor, the possibility existed for some thaw rigor to occur. In this study the possibility was small because the patties were frozen over a 10-20 hr period. Muscle pH was determined on the frozen, thawed and cooked samples to determine if the sample had reached its ultimate pH prior to freezing. This data is presented in Table 4. As expected, there were no significant differences in pH between hot and chilled patties. This is also reflected in the lack of significant differences in thaw loss (Table 3). If the hot processed patties had been frozen cryogenically thaw rigor might have been a problem. Research is in progress to investigate these possibilities. Percent fat and water did not differ significantly in the raw patty (Table 4) and percent fat was not different in the cooked patty. Percent moisture differed significantly in the hot and chilled cooked patty. This, of course, was illustrated in the differences in cooking loss (Table 3). One might expect that a patty from hot processed beef might contain more moisture in the raw as well as the cooked state. If this were the case, one could expect less nutrients from a certain size hot processed patty. Such was not the case, as shown by the data in Table 4. Undoubtedly, the hot and chilled patties were quite similar as to composition in the raw state but the chilled patty loses more water during cooking. This water results in lower juiciness and tenderness ratings and could possibly mean more patty left on the plate.

An evaluation of the effect of method of grinding on sensory, physical and chemical properties is presented in Table 5 and 6. Data for sensory and shear is outlined in Table 5. Method of grinding had no significant

affect on any palatability trait except flavor intensity. Patties prepared by Method 3 were less intense in flavor than Methods 1 and 2. This difference was probably a reflection of the absence of choice plates in the formulation rather than method of grinding. In any case, the difference was probably too small to be of practical importance. It is interesting to note that patties prepared from hot boned beef were more tender and juicy than patties prepared from chilled beef regardless of method of grinding.

Percent total cooking loss, height change, thaw loss and degree of doneness was not significantly affected by method of grinding (Table 6). Percent diameter change was greatest in patties prepared by Method 1 (Kidney plate x 0.32 cm). It is difficult to explain why the double grind should result in more diameter shrinkage than the triple grinds. A possible explanation could be the effect of the increased back pressure in the double versus the triple grind systems. Mean pH values of frozen, and thawed and cooked patties; and raw and cooked fat and water percentages were not significantly affected by method of grinding (data not presented).

It is quite evident from these data that beef patties can be prepared from hot processed beef that are equal to or superior to patties prepared from conventionally chilled beef in palatability, physical and chemical properties. Patties prepared from hot processed beef were significantly more tender and juicy and lost less water during cooking.

BACTERIOLOGICAL QUALITY OF GROUND BEEF PREPARED
FROM HOT & CHILLED BEEF CARCASSES

Introduction

Fabrication of beef carcasses before they are chilled ("hot" boning) could have several advantages as an alternative to conventional beef fabrication. Removal of excess fat and bone prior to chilling could save considerable energy in terms of total refrigeration. Additional advantages could include savings in costs of transportation, labor, and investment. In recent years researchers investigated the characteristics of hot-boned bovine muscle (1, 3, 5-10, 12). Most of these studies were concerned with the effect of hot boning on tenderness and eating quality of meat from Good and Choice grade beef carcasses.

The fabrication of ground beef utilizes a large proportion of the bovine carcass. Few, if any, data have been reported about the feasibility of producing ground beef from hot-boned beef carcasses. Such ground beef might have potential problems, which include textural changes, color differences and shelf-life, and inordinate bacterial counts would be prohibitive. We compared the bacteriological quality and shelf-life of ground beef prepared from hot- and cold-boned beef carcasses.

EXPERIMENTAL

PRODUCT FABRICATION

Four USDA Utility grade beef carcasses were used in this investigation. The animals were slaughtered and the ground beef was prepared and stored at

a commercial beef slaughter and further processing plant. At 2 hr postmortem, the top round, strip loin and ribeye cuts were removed from one side of each carcass. At 24 hr postmortem, the comparable muscles were removed from the sides that had been chilled at 3 C. The remainder of the meat from the boned carcasses was used immediately (2 and 24 hr postmortem) for the ground beef fabrication.

The hot-boned meat was chilled by addition of CO₂ snow (0.1 kg CO₂/kg meat) during ground beef fabrication. The hot-boned meat from the four sides (about 450 kg) was ground through a kidney plate. Two-thirds of the CO₂ snow was added, and the coarsely ground meat was mixed 3 min. The meat was then ground through a 1.27 cm plate, the remainder of the CO₂ snow was added, and the meat was mixed again for 3 min. The final grind was through a 0.32 cm plate, after which the ground beef was packaged in oxygen-impermeable polyethylene casings to make 5-lb chub packs. The ground beef from the four chilled sides was prepared in the same manner except that CO₂ snow was not used. Fat content of the ground beef was about 21 percent.

Forty-eight ground beef chub packs from the hot-boned batch and 48 from the cold-boned batch were stored at 0 C. Three chub packs from each batch were transported (45 min) to the laboratory for bacteriological analyses after 0, 3, 6, 9, 12, 15, 18, 21, 24, 27, 30, 33, 36, 39, 42, and 45 days of storage.

BACTERIOLOGICAL ANALYSES

Three locations within each chub pack were sampled aseptically to obtain a 25-g sample that was blended 2 min in 225 ml of sterile Butterfield's phosphate diluent (11). Serial dilutions of the samples were plated in duplicate on 3 sets of plate count agar (Difco Laboratories, Detroit, MI) plates.

Aerobic plate counts (APCs) were determined after the duplicate sets of plates were incubated 7 days at 5 C, 3 days at 20 C or 2 days at 35 C.

Most Probable Numbers (MPNs) of coliforms and Escherichia coli were determined by methods described in the Bacteriological Analytical Manual for Foods (4). All EC broth (Baltimore Biological Laboratory, Cockeysville, MD) tubes showing gas after 24 or 48 hr at 45.5 C were streaked onto Levine eosin methylene blue agar (BBL) for detection of typical E. coli colonies.

The logarithms (base 10) of the bacterial counts were treated statistically by analysis of variance (ANOVA) and Duncan's (2) multiple range test.

RESULTS AND DISCUSSION

There were no significant differences in initial APCs (5, 20, or 35 C) between the ground beef prepared from hot-boned and that prepared from cold-boned carcasses (Table 1). With one exception (APC 5 C at 3 days' storage) during the 45-day study, the APCs (5, 20, and 35 C) in ground beef from hot-boned were either significantly lower or not significantly different from APCs in ground beef from cold-boned carcasses.

The bacterial counts of the hot-boned ground beef did not increase as rapidly during storage as those of cold-boned. In hot-boned ground beef, APCs at 5 and 20 C did not increase significantly from 0-day counts until day 30 of storage at 0 C; APCs at 35 C were significantly higher than 0-day counts after 33 days. In ground beef from chilled carcasses, APCs at 5, 20, and 35 C were significantly higher than 0-day counts after 18, 21, and 24 days of storage, respectively.

After 45 days of storage, there were no significant differences in APCs (5, 20, or 35 C) between hot- and cold-boned ground beef, but the APCs were

slightly lower in the hot. Both products had reached the end of their microbiological shelf-life. During 45 days of storage, the APCs at 5, 20, and 35 C increased 2.55, 1.78, and 1.65 logs/g, respectively, in the hot-boned ground beef, and 3.08, 2.04, and 1.70 logs/g, respectively, in the cold-boned ground beef. The appearance and odor of both hot- and cold-boned ground beef were acceptable through 42 days of storage, but a slight off-odor was detected at 45 days.

MPNs of coliforms and E. coli were very low initially and throughout the 45-day storage study (Table 2). There were no significant differences of any practical importance in numbers of these bacteria between hot- and cold-boned ground beef.

Our data indicate that ground beef prepared from hot-boned carcasses as described above has bacteriological quality and shelf-life that are equal to or better than those of ground beef prepared from chilled carcasses. As an alternate processing method, fabrication of ground beef from hot-boned carcasses offer the meat industry great potential for energy conservation.

PHASE I - PART 3

Objective: To evaluate the effects of frozen lean source, patty size and patty treatment on palatability and cooking properties of ground beef patties.

THE EFFECTS OF FROZEN LEAN SOURCE, PATTY SIZE & PATTY
TREATMENT ON PALATABILITY & COOKING PROPERTIES OF
GROUND BEEF PATTIES

Introduction

The U.S. imports over 300 million pounds of frozen lean beef each year. Much of this imported beef is used in the production of ground beef. No research has been reported as to the effects on palatability and cooking properties of adding frozen lean from different sources. Also, patty sizes vary from less than 3.0 oz to more than 8 oz. It would be expected that patty size would have an effect on palatability and cooking traits. Little or no research has been reported in this area. The meat industry normally treats the fresh patty with a "knife-like" cut on each surface or a "waffle-like" impression on each surface. Research is needed to determine if these treatments have an effect on palatability and cooking traits.

This part of Phase I will address the questions of frozen lean source, patty size and patty surface treatment and their affects on ultimate palatability and cooking properties.

EXPERIMENTAL

FORMULATION

Fifteen ground beef formulations were prepared from varying raw material sources as outlined in Table 1. Formulations were prepared by adding 40% frozen lean (Mexican, Australian or domestic) to 60% choice lean trimmings

(unfrozen). Frozen lean was equivalent in grade to U.S. Cutter or Canner. Frozen lean was derived from the major and minor cuts of the entire carcass. Each formulation consisted of a minimum of 3000 lbs. Frozen meat blocks were passed through a Rietz grinder with a 3/8 in plate. Unfrozen, Choice trimmings were passed through a weiler grinder with a 3/8 in plate. Samples were randomly pulled after a 3 min mix and fat content was determined with an Anyl Ray Instrument. If necessary, the fat content was adjusted to $21 \pm 2\%$. The average temperature of the Choice trimmings after the first grind was 24° F. After mixing for 3 min with the frozen lean and grinding through the 1/8 in plate, the average temperature was 28° F.

Two 250 pound batches were randomly selected from the 3000 pound batch after the final grind. Each 250 pound batch was randomly allotted to one of three patty sizes (8.0, 4.0 or 3.6 oz). Ground beef was passed through a FORMAX 24 patty machine. The average pressure during patty formulation was 75 to 80 lb/sq in.

Immediately after the patties were formed the surface was treated in one of three ways (Table 1). The surface was either 1) left plain; 2) cut with a knife-like" blade or 3) cut with a "waffle-like" blade. The knife cut was deeper (approximately 0.25 in) but the diameter of the hole was smaller than the waffle. The waffle cut was wider but not as deep as the knife cut (less than .15 in deep).

After patty formation, the patties were immediately passed via conveyor belt into a Northfield Spiroblast Ammonia freezer (-50° F). The conveyor belt speed varied depending on the patty size. The internal temperature of the frozen patties averaged 20° F after 12 to 16 min. After freezing, patties were placed in plastic bags and stored at -10° F until shipment. Patties were

shipped to Beltsville, Md. via truck at 0° F. Patties were stored at -20° F until evaluated for sensory, physical and chemical properties.

COOKING METHOD & PROPERTIES

Frozen patties were broiled on electric Farberware grills. The time varied with the patty size. Preliminary trials indicated that in order to achieve the same degree of doneness, the 8.0 oz patty needed to cook 8 min on each side; the 4.0 oz patty 7 min; and the 3.6 oz patty 6 min. Degree of doneness was evaluated using an 8 point photographic scale with 8 = rare and 1 = well done. Degree of doneness was determined 5 min after sectioning. Total cooking loss was determined as the weight loss from the frozen to the cooked state. Measurements were obtained for raw and cooked patty height and diameter in order to evaluate changes during cooking.

PANEL SELECTION AND TRAINING

A 10-member panel was selected and trained in descriptive attributes by the procedures of Cross et al. (1978). The panel rated the following attributes on an 8-point structured scale: (a) tenderness and juiciness, with 8 = extremely tender and juicy; and 1 = extremely tough and dry; and (b) connective tissue amount with 8 = none and 1 = abundant. Panelists rated six samples at each of 18 sessions. Each treatment was replicated six times and samples to be evaluated in each session were selected via a table of random numbers.

INSTRON SHEAR

Ten patties from each treatment were broiled for determination of shear values. The cooked patties were cooled for at least 2 hr, and shear force was measured on each quarter of the patty with the single blade shearing device attached to the Instron as described by Cross et al. (1976b). Data were recorded for the maximum force required to shear through the meat patty.

STATISTICAL ANALYSIS

For each type of data, the analysis of variance was obtained using a sequential sums of squares approach. Since many of the contrasts were correlated, it was also necessary in the means analysis to use Scheffe's method to confirm in several instances that a difference between means was significant.

RESULTS & DISCUSSION

Table 2 presents data concerning the effect of frozen lean source on palatability traits. From the practical viewpoint, frozen lean source had no effect on palatability. There were a few significant effects but the magnitude of the difference is not important.

Frozen lean source from Mexico and Australia had significantly less total cooking loss than ground beef prepared from domestic frozen lean. Frozen lean from Australia had significantly less percent diameter change than patties prepared from domestic lean. Percent fat and water (as expected) was not significantly affected by frozen lean source.

Patty size had significant ($P < .05$) effects on tenderness, juiciness, amount of dectable connective tissue, and flavor intensity (Table 4). The 3.6 oz patties received significantly lower ratings in all of the aforementioned palatability traits when compared to the 4.0 and 8.0 oz patties. Patty size is likely more closely related to cooking and the ability of the patty to withstand high cooking temperatures.

As might be expected, as patty size decreased the percent cooking loss and percent diameter change increased (Table 5). Main effect interactions were highly significant ($P < .01$) for percent height change, thus further

means analysis is inappropriate. Degree of doneness ratings decreased (more well done) as patty size decreased--the only significant difference being between the 8.0 and 3.6 oz patties.

Patty treatments (knife, waffle or plain) did not enhance any palatability trait (Table 6). Untreated patties (plain) were more tender and juicy than patties receiving the knife or waffle treatment. The differences in connective tissue and flavor intensity were not significant but the trends were in favor of the untreated patty.

Patty treatments had non-significant effects on all cooking traits (Table 7). There appears to be no advantage (other than appearance) to subjecting the surface of the patty to a knife or waffle treatment. This data indicates that these treatments may actually have negative effects on palatability.

PHASE II - PART 1

Objective: Survey the current industry practices
pertaining to ground beef production.

SURVEY OF CURRENT INDUSTRY PRACTICES PERTAINING
TO GROUND BEEF PRODUCTION

Introduction

The tremendous expansion in consumer demand for ground beef has necessitated high-speed, large-volume product operations for ground beef. With this expansion has come variation in production systems. An interesting article appeared in the September 1976 issue of Meat Industry describing the many types of production layouts that are possible for ground beef depending on the volume of production.

During this past year, major commercial ground beef operations were interviewed and visited to determine the frequencies of certain processing systems, the type of equipment and raw material sources and the general comments concerning advantages and disadvantages of the systems.

SOURCE OF RAW MATERIAL

The majority of the commercial operations contacted utilize mature cow trimmings as the lean source with USDA Choice plates or 50% Choice trimmings as the fat source. While USDA Utility is the most frequent grade of cow used, several processors were using USDA Cutter and Canner grade beef. One-third of the 12 firms contacted used frozen rather than fresh cow meat; much of this being imported from Australia, New Zealand and South American countries. Some operations were using beef derived from the entire cow carcass, while others were using forequarter and hindquarter meat with the loins and ribs removed.

Still other companies used USDA Utility chucks, shanks and plates. Specifications often called for no visible tendons or ligament ends on shank meat. One processor using imported cow beef from a number of countries commented that he preferred Australian cow beef due to improved microbial levels and product texture. When frozen beef was used, it generally comprised 20-40% of the formulation.

PROCESSING SYSTEMS

Double grind systems seem to be the most prevalent in the industry. Considerable variation exists in the diameter of the initial grind with 0.63 cm, 0.95 cm, 1.27 cm, 1.59 cm, and 1.90 cm commonly used. Frozen beef is hydro-flaked prior to mixing with initial ground product where frozen and fresh beef are used together. Lean and fat sources are ground separately for the initial grind prior to mixing before the final grind. In operations that utilize chopping as the initial system of size reduction, 4-8 bowl revolutions are made where the bowl capacity is 800-2000 pounds.

CO₂ snow or pellets are used in some operations for temperature reduction, however, preliminary data at our laboratory indicate that patties formulated from product whose CO₂ has been added tend to have excessive crumbliness. This observation was verified by one processor. The final grind size is most frequently 0.32 cm although 0.24 cm and 0.20 cm plates were also used. Some firms use bone collector plates on the final grind although one major fast-food chain will not permit their use due to the creation of mushiness in the product. Mechanical disinewing does not appear to be a common process as yet in practice by the ground beef industry. Flaking of beef for ground beef production seems to be declining due in part to claims that uneven degrees of cooked doneness and product puffing occurs in patties made from flaked meat.

FAT ANALYSIS

Major ground beef processors use rapid fat analyzers in continuous production systems with Anyl Ray being the most frequently used. Tolerance range for fat is often 2-3% depending on the buyer.

PATTY FORMATION

Capabilities exist in the industry for various size and shapes of patties. Ten (45 g), five (91 g), and four (113 g) patties per 454 g are frequent sizes observed under industry practice. Perforations (knife and waffle) are also commonly used. Formax appears to be the most popular equipment line for patty production. Product temperatures between -1°C and 2°C are typical for proper patty production. However, some operations have been able to process patties as high as 5°C .

FREEZING & PACKING

5-7 lbs polyethylene bags and frozen

Industry practice in this area consists of individual quick freezing of patties cryogenically in freezing tunnels. Patties are usually stacked 15-20 high in cartons containing about 300 patties per box, although many operations may use containers with only 50 per box. Some processors are vacuum packaging long individual stacks of patties prior to storage. Most boxes are lined with a moisture polyethylene bag. Some processors shrink-bagging entire palletized volumes of boxes containing patties.

PHASE II - PART 2

Objective: To determine the effects of grinding, flaking and combinations of these two processes in the production of precooked and non-precooked beef patties made from Choice trimmings and Cutter and Canner cow trimmings.

EFFECTS OF GRINDING VS FLAKING IN THE PRODUCTION OF BEEF PATTIES

Introduction

Flaked, formed and cleaved steak-like products have been successfully produced in the meat industry. Flaking has also been used in some operations for the production of beef patties. However, some fast food establishments are no longer using flaked patties due to claims of uneven doneness in cooked product arising from patties swelling in the center during cooking. There have also been some claims that flaked patties do not hold together well especially in cookery.

The intent of this study was to evaluate to evaluate flaking vs grinding using beef materials differing widely in maturity (Choice vs Cutter-Canner cow) in the production of both raw-quick frozen and precooked-quick frozen patties.

EXPERIMENTAL

Raw materials for use in this project consisted of USDA Cutter and Canner cow forequarter and hindquarter beef, USDA lean trimmings from top sirloin butts and regular USDA Choice table (fat) trimmings. The Cutter and Canner cow meat average 8.7% fat, the Choice lean trimmings 7.9% fat and the Choice fat trimmings 38.5%. Formulations were processed to possess $24 \pm 1\%$ fat utilizing the Foss-let fat analyzer as the method of fat analysis.

Treatments that were ground were processed through a 1.99 cm plate initially followed by grinding through a 0.32 cm plate. The Cutter and Canner cow meat was frozen and thus was subjected to pre-breaking into pieces approximately 7.6 cm in all dimensions. Treatments were mixed for 2 min prior to final particle reduction steps.

Flaking was performed on the Urschel Commitrol 120 head where flaking was the final operation. Treatments that were flaked first and then ground were flaked using the Urschel Commitrol 750 head followed by final grinding with the 0.32 cm plate. Following grinding or flaking, 113 g patties were processed. In the case of patties to be frozen from the raw state, they were subjected to freezing at -38 C on a moving belt spiral freezer. Patties that were precooked prior to the same freezing process were cooked in a Heat and Control unit for a total time on a moving belt of 140 sec. The wet bulb temperature in cooking was 88 C, while the dry bulb temperature was 199 C. Product was stored at -26 C prior to the appropriate analyses.

Two batches were formulated per treatment. The Choice fat trimmings were used with the two lean sources to produce the 24% fat levels required. All combinations of source of lean trimmings, processing methods, state of product prior to cookery and batches depicted in Table 1 were processed.

Sensory panel training and procedures, physical measurements and chemical analyses for this phase and part were identical to those described in Phase I-Part 1.

RESULTS AND DISCUSSION

Tenderness scores did not differ substantially among the various treatment combinations (Table 2). In some comparisons by similar processing and state of product combinations, patties made from Choice trimmings had higher scores for tenderness than was the case for Cutter-Canner cow trimmings.

Connective tissue amount scores were also influenced more by source of lean trimmings rather than method of processing and state of product when cooked for evaluation. Flaking did not alter the connective tissue component, such that it was less detectable by the sensory panel.

Juiciness scores and rating for ground beef flavor intensity also were not greatly affected by the variable studied. Precooked patties, while essentially cooked twice received similar scores for juiciness as their counterpart cooked from the raw state for sensory analyses.

Instron values and cooking characteristics are presented in Table 4. Instron maximum shear force values and total work did reflect a higher degree of tenderness in formulations made from Choice trimmings in contrast to Cutter-Canner cow trimmings. With the exception of ground Cutter-Canner cow formulations, precooked patties had lower maximum shear and total work values than patties cooked from the frozen raw form just prior to evaluation.

Several interesting trends were apparent for cooking characteristics. Patties cooked from the frozen-raw state underwent greater change (reduction) in patty diameter during cooking than precooked and then recooked patties. However, the opposite situation was true for patty height. Thus, in essence, patties that were cooked from the frozen-raw state tended to shrink more from the outside periphery than the top and bottom in comparison to precooked patties. The differences between patty diameter changes and patty height changes in frozen raw vs precooked patties were less in ground formulations regardless of the source of lean trimmings.

As might be expected, the cooking losses were much greater for patties cooked from the frozen-raw state than was the case for precooked patties. This can be misleading since the weight loss during precooking has not been accounted for.

With the exception of Choice-ground-precooked patties having higher cooking losses than similar Choice precooked patties made from flaked materials, source of lean trimmings and method of processing did not affect cooking losses.

Chemical composition for fat and moisture values are depicted in Table 5. Values classified under "raw patties" would have received no cooking for raw product and one cooking for precooked product. Values under "cooked patties" would have been cooked once for raw product and twice for precooked samples. Cutter and Canner cow beef patties had higher moisture values in raw patties than was the case for patties in the raw form from all Choice materials. Precooked patties under the raw category were similar in percent moisture regardless of the source of lean trimming. This might imply that precooking removed more moisture in product made from cow trimmings than from Choice beef. This conclusion is verified by the values for percent fat on a wet basis for Cutter and Canner cow patties, where little differences exist between raw and precooked patties; while on a dry matter basis the percent fat is much lower in precooked than raw patties for these formulations. For patties made from Choice materials, flaking produced similar levels of moisture whether precooked or not, but resulted in much higher percentages of fat in the product on both a wet and dry matter basis. This would imply that for flaked Choice patties, precooking is removing more fat than is the case for patties manufactured from cow materials.

It is interesting to note that in comparisons under the category of raw patties vs cooked patties, raw patties decreased in percent moisture for the broiling type of cookery, while the precooked patties being cooked for the second time responded in the opposite manner for moisture values. Fat

levels generally went down substantially for the broiling cookery regardless of the state of the product. These results would indicate that in the second cooking (broiling) for precooked patties they are losing more fat in the cooking process than raw patties cooked by broiling for the first time. Values shown for TBA did not indicate a high degree of rancidity for any type of formulation.

CONCLUSIONS

Neither method of processing (grind vs flake) nor state of product when cooked for evaluation (precooked vs frozen-raw) exerted much of an effect on palatability, Instron values, or cooking characteristics in this study. Patties made from Cutter and Canner cow trimmings did have slightly lower tenderness as measured by sensory panel and Instron values.

Broiling the product from the frozen-raw state or the frozen precooked state produced the major differences in this phase of the project. Patties cooked from the frozen-raw state: 1) required less Instron force and work to shear samples; 2) shrunk more in diameter, but less in height; 3) possessed higher cooking losses; and 4) lost more moisture and less fat during cooking than comparable formulations cooked from the precooked state.

Phase II - Part 3

Objective: To ascertain the effects of grinding, chopping and combinations of these two processes in the production of beef patties made from Choice chucks and Cutter and Canner cow trimmings.

EFFECTS OF GRINDING VS CHOPPING IN THE PRODUCTION OF BEEF

PATTIES

Introduction

Several systems exist in the industry for initial partical reduction prior to the final grinding operation in the production of ground beef. Chopping of raw materials through the use of a food chopper or silent cutter has been used to produce "chopped beef" that has been packaged in keeper casings for distribution to other processors, retailers, etc., for final grinding. Industry comments relative to chopping have been favorable in terms of brighter color, less purge loss and longer shelf-life. However, research has not been conducted relative to assessing the importance of chopping in terms of palatability values. Thus, it was decided to evaluate chopping in comparison to grinding as the initial stage of particle reduction using Choice and Cutter-Canner cow materials.

EXPERIMENTAL

Raw materials for use in this phase consisted of USDA Cutter and Canner cow, forequarter and hindquarter beef, USDA chuck and neck trimmings and USDA regular chuck trimmings (52% fat). The Cutter and Canner cow meat averaged 10% fat, while the chuck and neck trimmings were 18% fat. Formulations were processed to possess $24 \pm 1\%$ fat utilizing the Any1 Ray fat analyzers as the method of fat analysis treatments that were ground were processed through a 1.58 cm plate initially followed by grinding through a 0.32 cm plate. All

treatments were mixed for 45 sec between the initial grinding or chopping and the final grind operation.

Chopping was performed in a 363.3 kg capacity chopper using 3 knives. Total chopping time was 30 sec or a total of 10 bowl revolutions. In treatments designated for chopping, after the chopping step, the materials were mixed for 45 sec prior to the final grinding procedure with the 0.32 cm plate. Patties (86 g) were processed and the product was stored at -26 c prior to the appropriate analyses.

Two batches were formulated per treatment. All combinations of the formulations, processing procedures and batches depicted in Table 1 were processed.

Sensory panel training and procedures, physical measurements and chemical analyses for this phase and part were identical to those described in Phase I - Part 1.

RESULTS AND DISCUSSION

In terms of definition for initial and final tenderness and connective tissue amount as assessed by the sensory panel, initial tenderness = rating after 5 chews, final tenderness = rating after 15 chews, initial connective tissue amount = rating after 15 chews, final connective tissue amount = rating after complete mastication of the sample by the panelist. Formulations made from all Choice materials received higher initial and final tenderness ratings than did patties made from Cutter and Canner trimmings with Choice trimmings added for fat adjustment. There was a trend especially for Choice formulations of higher tenderness scores for product initially chopped rather than ground or ground and chopped combined. Scores assigned for initial tenderness did not

appreciably differ from those for final tenderness.

Connective tissue amount scores, both initial and final also reflected higher values (less organoleptically determined connective tissue) for both Choice vs Cutter-Canner formulations and chopped vs grind and 50% grind - 50% chopped treatments. It would appear that chopping the material prior to final grinding does create changes in the connective tissue where they are slightly less detectable in the final patty product. There were some batch differences for Choice 50% ground - 50% chopped and Cutter-Canner chopped than ground formulations.

Juiciness scores were not greatly affected by the treatment variable of this study, although Cutter-Canner ground and 50% ground - 50% chopped formulations received the lowest ratings for juiciness. Cutter and Canner formulations yield patties rated lower in flavor intensity than companion patties made from all Choice trimmings.

Instron maximum shear force measurements essentially revealed no differences among sources of raw material or processing methods. However, total Instron work values indicated greater work (lower tenderness in treatments manufactured from Cutter and Canner cow trimmings. Visual scores for degree of doneness were influenced more by batch than any of the other variables studied. It is interesting to note that patties processed by chopping and then grinding Cutter and Canner cow beef had the least change in patty height upon cooking and were also low in cooking loss. Muscle from older maturity cattle is reputed to have better water holding capacity and chopping has been acclaimed to produce less purge loss than grinding.

Differences in the percent moisture in cooked patties appeared to be influenced as much by batch as source of lean and processing method. There was

a slight trend on a dry matter basis for treatments initially all chopped prior to grinding to have more fat in the cooked product than was the case for other treatments.

CONCLUSIONS

Generally, grinding, chopping or a combination of grinding and chopping as the initial particle reduction system did not greatly affect palatability, physical or chemical values. There was some tendency for chopping to yield slightly higher tenderness scores and less organoleptically assessed connective tissue than grinding. Patties made from all Choice materials had higher tenderness scores, less detectable connective tissue ratings and lower total Instron work than similar patties made from Cutter-Canner cow trimmings with Choice fat trimmings. In summary, it would appear that chopping as an initial system of reducing trimming size is as good or slightly better from a palatability standpoint as the double grind system.

TABLE 1. Experimental design.

Source of trimmings, formulations	Processing procedures	Batches
USDA choice chuck lean trimmings with USDA choice chuck fat trimmings	Initial grind--1.58 cm followed by final grind of 0.32 cm.	1, 2
USDA cutter and canner cow trimmings with USDA choice chuck fat trimmings	Chopping (30 sec.--10 revolutions) then final grind--0.32 cm.	
	Divide the lean and fat trimming in half. Chop 50% of the trimmings (30 sec.--10 revolutions). Grind 50% of the trimmings--1.58 cm. mix together and final grind 0.32 cm.

PHASE VI - PART 1-FAT SOURCES

Objective: To determine the effects of 5 sources of fat:

- 1) Choice plates; 2) Choice trimmings;
- 3) Choice flanks; 4) 50-50 Choice trimmings with kidney fat; and 5) 50-50 kidney fat with brisket fat on ground beef quality.

PART 2-FAT LEVELS

Objective: To determine the effects of various levels of fat (12, 18, 24, and 30%) on ground beef quality.

EFFECTS OF VARIATIONS IN FAT LEVEL AND SOURCE ON GROUND BEEF QUALITY

Introduction

Several studies in the past have attempted to determine the major quality characteristics consumers look for when purchasing ground beef. Glover (1964) determined that the primary attribute consumers associate with ground beef quality is the degree of leanness. Mize (1972) and Law et al. (1965) revealed that consumers identify color first, and leanness second in the area of quality. USDA regulations stipulate that 30% fat is the maximum allowable fat level in ground beef.

Research by numerous workers has shown that consumers can distinguish ground beef manufactured with different fat levels. Cole, Ramsey, and Odom (1960) determined that consumers preferred ground beef containing greater than 15% fat, while a trained sensory panel preferred patties in direct proportion to fat content with product manufactured at 35% fat receiving the highest scores for palatability. Their study concluded that leaner ground beef is generally less palatable than ground beef containing at least 25% fat. Mize (1972) and Law (1965) found that consumers preferred ground beef in the following order according to fat level; 15%, 25% and 35%. Additional research by Glover (1964) demonstrated that consumers preferred ground beef containing 20% when compared with ground beef formulated to 16, 25, and 30% fat levels. There has been little if any research conducted to determine the effect of fat source or type on ground beef quality. The objective of this study was to determine the effects of type and level of fat on ground beef quality.

EXPERIMENTAL FOR PART I AND IIGRINDING

USDA Utility chucks, Choice plates, Choice trimmings, Choice flanks, kidney and brisket fat were purchased and trucked to the abattoir at the Beltsville Agricultural Research Center. All raw materials were ground through a 1.9 cm plate, during which a 5.9 kg grab sample was collected for fat analysis. The fat content was estimated by the Anal-Ray fat analyzer. Treatments (22.7 kg in size) were then formulated to contain 12, 18, 24, or 30% fat by mixing the Utility chucks with one of the fat types for a total of 3 min. The meat was then ground through a 0.32 cm plate, after which 145 gm patties were formed on the Hollymatic No. 200 patty machine, boxed, and frozen at -24° C. After 24 hours 3 patties per package were wrapped in butcher paper, boxed and stored at -13° C.

The procedures for cooking, chemical analysis, physical changes, and sensory panel evaluation were generally the same as those described under Phase I, Part I. The percent diameter change, percent height change, and final cooked temperature were not measured. Cooking times to achieve the same degree of doneness varied with the percent fat. Patties containing 24% fat were broiled 8 min on one side turned and broiled 6 min on the other side; 30% fat broiled 7 min on one side turned and broiled 5 min on the other side; 12% fat broiled 5 min on one side turned and broiled 5 min on the other side, turned and broiled 5 more min on the first side; and 18% fat broiled 4 min on one side turned, broiled 4 min on the other side; turned and broiled 6 min more on the first side. The sensory evaluation panel only evaluated final tenderness, final connective tissue amount, juiciness, and ground beef flavor intensity (refer to Phase I, Part 1). In addition panelists evaluated the degree of coating of their mouths.

RESULTS AND DISCUSSION PART I

Table 2 shows the results of palatability and Instron measurements on ground beef. Tenderness was not affected by the fat source used, however, the 30 percent fat level yielded higher ($P < .05$) tenderness ratings for 50-50 Choice trimmings/Kidney fat and 50-50 brisket fat/kidney fat than product made to have 24 percent fat. Instron total work values also reflected greater tenderness in product possessing 30% fat vs. treatments with 24% fat. Juiciness also was only significant ($P < .05$) for fat level, with patties made to have 30% fat yielding higher juiciness scores than 24% fat product. Ground beef flavor intensity scores, connective tissue amount scores, degree of doneness scores and cooking loss percentages were not significantly ($P > .05$) different for fat source or fat level (data not shown). Since sensory panel scores for connective tissue amount revealed no difference due to the type of fat, no chemical determination of connective tissue was done. Table 3 shows that the type of fat, rather than the level of fat, influenced sensory scores for mouth coating due to fat. Product made from choice plates were scored significantly lower ($P < .05$) than product using Choice flanks as the fat source with Choice flanks rated higher ($P < .05$) 50% brisket fat-50% kidney fat product. It should be noted that the magnitude of the difference between fat sources, 6.19 to 6.41, is of no practical value.

The percent fat was determined by ether extract to confirm that treatments were formulated to 24% or 30% fat (Table 4). When ground beef patties were cooked the percent fat was reduced for all treatments, with the 30% fat treatments generally retaining more fat than 24% fat treatments post cooking. The percent moisture was also determined (Table 5). Increased fat content resulted in lower percent moisture raw, as would be expected. The percent moisture decreased when ground beef patties were cooked.

CONCLUSIONS

The results of the data indicates that the type of fat used in the manufacture of ground beef does not affect the quality of ground beef. Scores for mouth coating due to fat were the only parameter in which a significant difference due to the type of fat was found, however, the magnitude of the difference was of minor importance. Level of fat in the formulation (24% vs. 30%) did have a significant effect on tenderness, juiciness, shear force, and total shear work, with 30% fat having higher palatability scores and reduced Instron values. The effect of fat level will be discussed in more detail in part II.

RESULTS AND DISCUSSION PART II

Four treatments of ground beef were formulated to contain 12, 18, 24 and 30% fat as discussed under the Experimental portion pertaining to grinding in parts I and II. Chemical determination of the percent fat, by ether extract revealed that the treatments were in fact formulated to 16, 20, 24 and 30% fat (Table 6). Throughout the rest of the paper these treatments will be referred to as 16, 20, 24 and 30% fat. The % moisture of raw ground beef patties was highest for the 16 % fat treatment. Upon cooking, all treatments lost moisture, with the 16% fat treatment retaining the most moisture after cooking (Table 7). The results of sensory panel evaluation and Instron mechanical shear are shown in Table 8. Tenderness was affected by the % fat in ground beef, with the 16% fat treatment being significantly ($P < 0.05$) less tender than either 24% or 30%. Sensory panel scores for juiciness were significantly ($P < 0.05$) lower for patties containing 16% fat compared to all other treatment scores. In addition patties containing 30% fat received significantly ($P < 0.05$) higher scores for juiciness than all other treatments. Since

patties processed to contain 16% fat had less moisture, these results would support the positive effect fat has on juiciness. There was significantly more ($P < 0.05$) detectable connective tissue in patties formulated to 16% fat than 24 % or 30%. The magnitude of the difference between all four treatments for detectable connective tissue amount is of minor importance. However, patties containing 24% fat received the highest scores for connective tissue amount and it had the lowest total amount of chemically determined total collagen (Table 9). Scores for mouth coating due to fat were significantly ($P < 0.05$) higher for 30% fat samples compared to all other treatments. This could be attributed to the fact that patties containing 30% fat had the most fat of all four treatments evaluated. Treatments formulated to 24 and 30% fat required significantly less ($P < 0.05$) total Instron work to shear than was the case for patties made to have 16 or 20% fat. Mention should be made of the relationship between Instron total work and sensory panel scores for tenderness. As the % fat increased, total work decreased and sensory panel scores increased, reflecting a more tender product. The ground beef flavor intensity, degree of doneness, Instron shear force (Kg) and % cooking losses were all nonsignificantly ($P > 0.05$). (data not shown) It was surprising to note that ground beef containing different percentages of fat did not differ in % cooking loss. Partial explanation for this phenomenon can be seen in Table 10. The lower the % fat in ground beef, the less fat was lost and the more moisture was lost during cooking. On the other hand, increasing levels of fat in ground beef resulted in more fat lost and more moisture retained when cooked. Generally, the patties are cooked, the fat which is lost accumulates in the pan during frying and may be visible to the housewife, whereas the moisture lost is not visible. Glover (1964) determined that consumers dislike ground beef containing high levels of fat because of excessive

shrinkage when cooked. The data presented here reveals that in fact there is no difference in the total cooking loss of patties containing 16, 20, 24 or 30% fat. However, it is likely that the visible cooking loss, (fat drippings) is different and greatest in patties possessing 30% fat.

CONCLUSIONS

As the % fat increased in ground beef from 16 to 30% fat tenderness and juiciness scores assigned to cooked patties increased, while Instron total work decreased. Since total losses in cooking did not differ among the various fat levels of this study, product manufactured to contain 30% fat may have a higher ratio of edible portion to cost because 30% fat ground beef usually is priced lower than product at 24% and lower fat levels.

PHASE VI - PART 3-STORAGE

Objective: To access the effects of storage on palatability of ground beef formulated from five different fat sources: 1) Choice plates; 2) Choice trimmings; 3) Choice flanks; 4) 50% Choice trimmings with 50% kidney fat and; 5) 50% brisket fat with 50% kidney fat (Part 1) and four levels of fat (16, 20, 24, and 30%) (Part 2).

EFFECTS OF VARIOUS PERIODS OF FROZEN STORAGE ON PALATABILITY
AND CHEMICAL VALUES OF GROUND BEEF PATTIES

INTRODUCTION

The ground beef treatments discussed under Phase VI Parts I and II, were reevaluated by the sensory taste panel at 3, 6 and 9 months. In addition, TBA values were also determined at 3, 6 and 9 months.

RESULTS AND DISCUSSION OF STORAGE FOR PART I, FAT SOURCES

In general, if ground beef has a TBA value of 2.00 or greater a sensory panel should be able to detect rancidity in the product. As time of storage increases, TBA numbers should increase, reflecting increased rancidity due to prolonged storage. It can be seen from Table 1, that TBA values decreased over time, this can be attributed to either further breakdown to free fatty acids or the perhaps inappropriate procedure of Tarladgis (1960).

Table 2, reveals that as time increased ground beef flavor intensity decreased. This is a result of the increase in detectable off-flavors, mainly rancidity, as time increased (data still being analyzed). In general, storage of ground beef patties formulated from various fat sources, did not affect tenderness, juiciness, connective tissue amount, degree of doneness, or the percent cooking loss (Tables 3 - 7).

CONCLUSION

The 9 month storage of ground beef patties formulated from Choice plates, Choice trimmings, Choice flank, 50-50 Choice trimmings/kidney fat

or 50-50 brisket fat/kidney fat, did not generally increase or decrease sensory panel scores for tenderness, juiciness and detectible connective tissue amount. Cooking parameters of % cooking loss and degree of doneness were generally not affected by storage. The major problem associated with storage was the general decrease in ground beef flavor intensity after 3 months and the increase in off-flavors detected by the panel. If the development of off-flavor could be curtailed ground beef could be stored up to 9 months without generally affecting other palatability traits of ground beef. In general fat source did not affect the palatability or cooking characteristics of stored ground beef.

RESULTS AND DISCUSSION OF PART II, FAT LEVEL

Table 8, shows the TBA values for ground beef, formulated to possess fat levels of 16, 20, 24 and 30% over a 9 month storage period. Again, TBA values decreased instead of increasing as would be expected (refer to results and discussion Part I). In general, ground beef flavor intensity decreased as time increased (table 9). The difference in ground beef flavor intensity between fat levels was small (0.4 maximum). The general decrease in flavor intensity can be related to the increased frequency of off-flavors, predominantly rancidity, as time increased (data still being analyzed). Scores for tenderness and juiciness (Tables 10 and 11) respectively showed a slight tendency to decrease with prolonged freezer storage. The fat level of ground beef did tend to affect the tenderness and juiciness scores within each time frame. However, the sources at 0 month were similar to those noted at 9 months. For example, patties made at 16% fat received a mean tenderness score of 4.9 at 0 month, the lowest of all four scores, and it remained the lowest for each time period (5.2 at 3 month., 4.9 at 6 months

and 4.6 at 9 months - Table 10). In gneral, detectable connective tissue amount was not affected by time, however fat level did affect sensory panel scores for connective tissue amount. Again, the differences in connective tissue amount due to fat level established at 0 month remained approximately the same at 3, 6 and 9 months (Table 12). As a whole the degree of doneness and % cooking loss were not affected by the length of storage (Tables 13 and 14).

CONCLUSIONS

The 9 months storage of ground beef patties containing 16, 20, 24 or 30% fat resulted in an increased incidence of off-flavors, reduced tenderness and juiciness scores. The effects of various fat levels noted at 0 months remained about the same at all successive time intervals. In summary ground beef can be formulated with either Choice plates, Choice flanks, Choice trimmings, 50% Choice trimmings with 50% kidney fat or, 50% brisket fat with 50% kidney fat without affecting the quality of ground beef. Ground beef should be formulated to 20% fat or more to maximize palatability attributes and not stored over 3 months to avoid development of off-flavors.

PHASE VI - PART 4

SHELF-LIFE OF PARTS 1 & 2

Objective: To evaluate the shelf-life characteristics of ground beef prepared from raw materials varying as to anatomical location and level of fat.

SHELFLIFE CHARACTERISTICS OF GROUND BEEF MANUFACTURED FROM
TRIMMINGS VARYING IN ANATOMICAL LOCATION AND
LEVEL OF FAT

Introduction

The vast array of processing procedures and types of trimmings for ground beef provides an excellent environment for the growth of bacteria. The grinding and mixing operations used in ground beef processing permits a rather complete distribution of microorganisms into the product. Several studies have shown high bacterial counts in ground beef normally distributed through retail channels (Rogers and McClesky, 1957; Rao, 1970; Duitschaeffer, et al., 1973; and Law, et al., 1971). However, Emswiler, et al. (1976) found that proper sanitation and refrigeration will permit prolonged shelflife of ground beef.

While many possibilities exist for contaminating beef trimmings intended for ground beef, little information is available as to whether certain anatomical sources of the trimmings and the level of fat in the final product exert an influence on shelflife characteristics.

EXPERIMENTAL

Sources of raw material and procedures for the manufacture of the ground beef have been previously described under the Phase VI report.

Grab samples for microbiological analyses were aseptically taken from each treatment following product mixing just prior to the final grind. Samples

(25 g) were blended for 2 min. with 225 ml of sterile Butterfield's phosphate buffer. Serial dilutions of the samples were plated in duplicate on 3 sets of plate count agar (Difco Laboratories, Detroit, MI). Plates were incubated at 20°C for 3 days prior to enumeration.

Following the final grind, 454 g samples were wrapped in retail film wrap and stored at 3°C under 90 foot candles of incandescent light. The lights were turned on over the product for 12 hours each day for the 3-day duration of the shelflife study.

Each day a trained three-member panel evaluated the packaged samples for color, amount of surface discoloration and lean and fat distribution. On the third and final day of the storage period, the panel opened the packages and scored the degree of off-odor in the product. The scoring systems for these shelflife characteristics are presented in Table 1.

RESULTS AND DISCUSSIONS

Generally a two-three log increase in bacterial numbers occurred between zero and three days of retail display (Table 3). At the time of initial processing, formulations of Utility chucks-Choice trimmings-Kidney fat and Utility chucks-Kidney fat-Brisket fat had higher mean bacterial counts than other formulations when processed to possess 24% fat. This difference was also observed following three days of display. However, formulations containing kidney and brisket fat were generally lower than most of the other formulations when processed to possess 30% fat regardless of length of storage. No explanation is apparent at this time to explain this result. The 30% formulation level would have more brisket and kidney fat than the 24% level. Brisket fat has more water and kidney fat contains more saturated fatty acids than the other fat which might exert subtle changes in product composition that could affect bacterial numbers.

The distribution of lean and fat was not affected by formulation, level of fat and days of storage (Table 4). There was a tendency for the distribution patterns to be more even at the lower levels of fat, but these differences were nonsignificant ($P > .05$). While kidney fat is certainly a much whiter fat than brisket fat, the evaluation team did not find any visible differences in the distribution of these sources of fat in the final ground product.

The mean values for product color by level of fat with days of storage is depicted in Table 5. This interaction effect was nonsignificant ($P > .05$). However, when averaged across storage level, each level of fat differed ($P < .05$) in color score from all other levels. A linear effect was shown in that as fat level increased, lighter color scores were assigned. Certainly, the dilution of the darker lean with increasing fat explains this result. In addition, formulations containing kidney and brisket fat received darker color scores than product incorporating Choice flanks (3.66, 3.48 vs 5.76). Also scores assigned following three days of display were darker than the panel values assigned at zero and one day of display (3.44 vs 4.98, 4.73).

The interaction effect of storage time with level of fat also proved nonsignificant ($P > .05$) for surface discoloration (Table 6). Level of fat and source of formulation trimmings were not influential on surface discoloration scores. As expected, a significantly ($P < .05$) greater amount of discoloration occurred over the three-day storage period (0 day = 7.30, 1 day = 6.46, 2 day = 5.54, 3 day = 3.93).

While source of formulation materials did not affect the presence of off-odor in the samples, higher levels of fat tended to have higher frequencies of off-odors (Table 7). This trend was significant ($P < .05$) between the 30 and 12 percent fat levels. Since much of the off-odor is a result of bacterial spoilage, lipolytic organisms were possibly quite prevalent in the microbial population of the samples. The significant relationship between off-color and

bacterial counts is shown in Table 8. Likewise samples displaying considerable surface discoloration also had higher bacterial counts. Since much of the discoloration was a change from red to brown and green pigments, the color scores were also highly correlated to surface discoloration.

Storage time appeared to exert more of an influence on shelf-life characteristics than source of product trimmings and level of fat. However, formulations containing kidney and brisket fat had higher bacterial counts when formulated to 24% fat and were darker in color at the completion of the shelf-life study. Higher incidences of off-odor were associated with higher levels of fat in the product.

Running Head: Ground Beef Palatability

Key Words: ground beef, peanut meal, soy protein, mechanically
deboned meat

Ground Beef Palatability

1. INTRODUCTION

2 Sufficient animal protein is available to supply the nation's
3 protein requirement, but, socio-economic circumstances may cause
4 an uneven distribution among the population (Bird, 1974). Also, even
5 in an affluent society such as ours, questions arise concerning the
6 waste of useful products. Therefore, much attention has
7 recently been given to methods of recovering and utilizing various
8 kinds of proteins in ground and comminuted meat products.

9 Bird (1974) estimated that by 1980 about two million
10 pounds of meat will be replaced by various plant proteins. Most agree
11 that soy protein is and will remain the most widely used of these
12 plant protein additives for ground beef production. Obviously, one of
13 the most important factors affecting this usage is palatability. Soy
14 protein from 2 to 30% was tested for palatability and variables such
15 as family income and its effect upon consumer acceptance were considered
16 (Mize, 1968; Twigg et al., 1977). These previous studies showed that
17 addition of various soy proteins to ground beef is feasible in terms
18 of consumer acceptance. Tenderness was improved with the addition
19 of soy (Mize, 1968; Huffman and Powell, 1970; Twigg et al., 1977;
20 Cross et al., 1975) and other sensory panel parameters were minimally
21 affected. Color problems and flatulence factors, however, have been
22 associated with soy protein. Also, the high carbohydrate content of
23 soy leads to severe bacterial spoilage. A new commercial process has
24 been devised to remove most of these carbohydrates. In this process
25 the soy flour is acidified (to the isoelectric pH) and the precipitate
26 is collected and pressed into a fiber. The resulting product, termed

Ground Beef Palatability

1 "soy protein fiber" is 90% protein with a pH of 5.2. The structure
2 of the soy additive as "fiber" is hoped to increase the textural
3 desirability of food products. Substitution of the soy protein
4 fiber for beef has not been evaluated for its effect on the textural
5 qualities of ground beef.

6 Research in the area of plant protein addition to ground beef
7 is not entirely limited to soy. McWatters (1977) found that patties
8 containing steam-heated peanut meal were similar in palatability to
9 all beef patties and to patties containing a soy protein additive.
10 Commercial advocates of "flaked peanut meal" maintain that in contrast
11 to the traditional soy additives, peanut meal has enough fiber to
12 add texture to food products. Also, peanut meal does not possess
13 flatulence factors and sustains a long shelf-life. Processing methods
14 for flaking of peanuts are presently being developed.

15 Mechanical deboning of beef has been suggested as a means of
16 reducing protein waste by recovering meat and marrow from bones
17 (Field, 1976; Fried, 1976). Many large packing facilities at one
18 time were equipped with mechanical deboning machines. Cross et al.
19 (1977) reported that sensory panel members preferred ground beef
20 patties containing up to 20% added mechanically deboned beef to the
21 controls.

22 Addition of soy protein, peanut meal, and mechanically deboned
23 beef increases the tenderness of ground beef patties as indicated
24 in the previous studies cited. Excessive substitution of an additive
25 for beef, however, may cause undesirable mushiness. The objective of
26 this study was to compare the effects of soy protein fiber (SPF),

Ground Beef Palatability

peanut meal (PM), and mechanically deboned beef (MDB) upon ground beef texture. Combination of the MDB with SPF and with PM were also tested.

EXPERIMENTAL

Product Formulation

Two hundred kg of hand deboned beef from USDA Choice grade chucks were coarse ground through a 2.54 cm plate and thoroughly mixed in a Hobart Mixer-Grinder (model 4346). This procedure insured that all treatments were of an identical lean source. The coarse ground beef was then randomly divided into 15 batches weighing approximately 13 kg each. The formulations listed in Table 1 were prepared by adding in the appropriate levels of MDB, SPF, and PM to 14 of the batches on a percent weight basis. The remaining batch (treatment 1, Table 1) did not have any amount of MDB, SPF, or PM added to it and thus served as a control of 100% beef. The PM was dehydrated Nutrex precooked peanut flakes and was added on a hydrated basis (1 part PM to 1 part water). The SPF was supplied by the Ralston Purina Company and was added on a dry weight basis. Combinations of MDB with SPF and MDB with PM were also tested. None of the treatment groups required the combination of SPF with PM. After the appropriate levels of MDB and/or PM or SPF were added, the batches were separately mixed for 1 min; ground through a 1.9 cm plate; mixed for 1 min; and finally ground through a .32 cm plate. Patties weighing 114 g and .95 cm in thickness were prepared in a Hollymatic patty machine (model 200). Patties were frozen and stored at -20 C until needed for sensory and chemical analysis.

Ground Beef Palatability

1 Trained Panel

2 An eight member sensory panel, trained by the procedures of
3 Cross et al. (1978), evaluated samples from each treatment in a
4 total of 15 sessions; six samples were evaluated per session.
5 The control was replicated 11 times and the treated groups either
6 5 or 6 times as determined by a random numbers table. The
7 parameters evaluated were: tenderness (8 = extremely tender, 1 =
8 extremely tough); juiciness (8 = extremely juicy, 1 = extremely dry);
9 and cohesiveness (8 = extremely cohesive--mushy, 1 = extremely unco-
10 hesive--coarse). Due to the particle size and texture of MDB, addition
11 of large amounts to ground beef could lead to a "mushy" product (Cross,
12 et al., 1977). This concern also applies to some plant proteins (Cross
13 et al., 1975). The sensory panel was trained to evaluate those possible
14 differences as cohesiveness. Patties served to the sensory panel
15 were cooked from the frozen state on electric Farberware grills (275 C)
16 for five minutes per side.

17 Cooking Losses and Shear

18 Cooking loss from the frozen to the cooked state was determined
19 by weighing ten patties per treatment before and after cooking. Each
20 of the 10 patties were pictorially scored for degree of doneness
21 (color photographs with 1 = well done and 8 = rare) by a well trained
22 observer. The patties were then sectioned into four 2.54 cm squares
23 and the resulting 40 sections were measured for maximum shear and
24 area under peak curve using the Instron single blade technique of
25 Cross et al. (1978).

Ground Beef Palatability

Chemical Analysis

Moisture per cent was determined by weighing four 3 g samples before and after drying in a 102 C oven for 24 hours. Fat percent was determined by weighing the four 3 g samples before and after a 12-hour fat extraction in diethyl ether. Fat levels were expected to vary due to the addition of the extra protein sources.

Statistical Analysis

Sensory panel, degree of doneness, percent fat and percent moisture mean values for each of the 15 treatment formulations were tested for significant differences by the analysis of variance (ANOVA) followed by Duncan's multiple range test (Duncan, 1955). In the Results and Discussion, the results from this statistical procedure for sensory panel data will always refer to the comparison between the means of the specific treatment formulations listed.

In addition, the ANOVA procedure of Klotz and Teng (1977) was performed to test the individual effects of each additive. This ANOVA process determines if a significant response is given by adding varying levels of additive. Discussion based on this type of statistical analysis will not associate an additive with a percent level of addition but will refer to the general effects or "overall" response given by the sensory panel over the range in which it was added.

RESULTS AND DISCUSSION

Tenderness

Mean values from the trained sensory panel for tenderness are listed in Table 2. In agreement with Cross et al. (1977), ratings for tenderness were significantly ($P < .05$) higher for patties containing

Ground Beef Palatability

1 30% MDB than the mean value of the control product. Patties containing
2 20 or 30% MDB did not differ in tenderness. The mean value of 5.1
3 for the control treatment approached an unacceptable level of tenderness.
4 Overall, the addition of peanut meal (PM) significantly ($P < .01$) improved
5 tenderness, but patties containing 5% PM were similar to the control.
6 Patties with 10% PM were rated significantly ($P < .05$) more tender than
7 the control. Overall, the addition of soy protein fiber (SPF) to the
8 formulation significantly ($P < .001$) decreased tenderness. Patties
9 containing SPF at both the 5% and 10% levels were rated less tender
10 than the control and patties containing either MDB or PM alone. Those
11 differences often were large enough to be important.

12 The addition of MDB at both the 20% and 30% levels improved the
13 tenderness of patties containing 5% or 10% SPF. This improvement was
14 significant ($P < .05$) for 10% SPF plus 30% MDB vs 10% SPF alone. The
15 improvement in tenderness also was significant between 10% SPF and
16 30% MDB vs 10% SPF and 20% MDB. Tenderness for patties containing 5%
17 PM was significantly improved with the addition of either 20% or 30% MDB,
18 but this was not the case for the 10% PM level. However, the combin-
19 ation of 10% PM plus 30% MDB yielded the highest mean tenderness value
20 of any treatment.

21 Our data from tenderness evaluation suggest that: (1) addition of
22 MDB and/or PM improved tenderness, (2) SPF decreased tenderness, and
23 (3) the addition of MDB to SPF formulations tended to offset the
24 negative effect of SPF. Those conclusions are supported by ratings of
25 the trained sensory panel and by the Instron measurements of shear force
26 and area.

Ground Beef Palatability

1 Juiciness

2 MDB did not have a significant effect on juiciness (Table 3).
3 Mean values for patties containing 0% (control), 20% and 30% MDB did not
4 differ. Furthermore, addition of PM did not significantly affect
5 sensory panel juiciness scores. Mean values for juiciness did not differ
6 between 0% (control), 5% and 10% PM. Addition of SPF to the ground
7 beef patties significantly ($P < .001$) decreased sensory panel juiciness
8 scores. Patties with 10% SPF were rated significantly lower in juiciness
9 than the patties with 0% (control) or 5% SPF. The negative effect of SPF
10 on juiciness might be attributed to the low pH of the SPF additive.
11 Combining SPF with MDB generally improved sensory panel juiciness
12 over that of SPF added alone.

13 Cohesiveness

14 Similar to sensory panel tenderness results, MDB was significantly
15 ($P < .05$) linear in its effect on sensory panel cohesiveness (Table 3).
16 Patties containing 30% MDB differed significantly ($P < .05$) from the
17 control in cohesiveness. In agreement with Cross *et al.* (1977), this
18 result may indicate that addition of MDB at 30% or higher may lead to
19 mushy ground beef. The increased tenderness achieved by adding MDB may
20 be attributed to its tendency to produce a mushy texture due to its
21 small particle size. This occurrence may not be detectable up to 20%
22 added MDB. Patties containing 20% MDB were similar to both 30% MDB and
23 the all-beef control. The addition of SPF alone did not significantly
24 affect cohesiveness. The mean values for patties containing 5% or 10%
25 SPF were similar to the mean value of the control. Therefore, it could
26 be concluded that addition of SPF does not increase the coarseness of

Ground Beef Palatability

ground beef although its addition yields a less tender product. Combination of SPF with 30% MDB increased the cohesiveness of the ground beef patties. Patties containing 10% PM had significantly ($P < .05$) larger mean values for cohesiveness than those containing 5% PM or the control. This may indicate that similar to MDB, substitution with PM at high levels may yield a mushy texture. Combinations of PM and MDB resulted in the highest mean values of all treatments for cohesiveness.

Cooking Properties

Addition of higher levels of MDB and SPF alone resulted in lower ratings for degree of doneness (Table 4). These decreases were significant ($P < .05$) between MDB at 30% vs MDB at 20% and the 0% control. Similarly, SPF at 10% was significantly lower than 5% SPF and the control. Patties with PM at 10%, however, were significantly higher (less well done) than PM at 5%. Although data were not treated statistically, formulations containing SPF appear to have sustained less cooking loss than formulations without SPF (Table 5).

Conclusions

Conclusions based on these data are: (1) addition of MDB or PM alone increased the tenderness and cohesiveness of ground beef patties but did not affect juiciness, (2) addition of SPF decreased tenderness and juiciness but did not affect the cohesiveness of ground beef patties.

Key Words: Ground beef, precooking, palatability

Running Head: Precooked Beef Patties

Introduction

There has been increased interest in the meat industry to produce precooked meat items for use by the institutional trade. Several elementary and secondary schools in the U.S. are using precooked, frozen beef patties rather than frozen, raw beef patties. Some advantages cited in favor of precooking are reduced cooking time prior to serving and fewer cooking losses. There is almost no published research data to support these statements. Soy added to meat may reduce the stale or warmed-over flavor in reheated meat because certain vegetable extracts are effective antioxidants. Sato et al. (1973) found that adding one of several cereal protein products to ground-meat loaves prevented rancidity. Bowers and Engler (1975) added soy protein to raw patties that were subsequently either cooked or precooked, frozen, and reheated and found the reheated patties to be less juicy regardless of the amount of soy in the formulation. The soy-containing patties that were not precooked also had less meaty aroma and flavor than the all beef controls (Bowers and Engler, 1975).

To our knowledge, no one has evaluated the palatability of patties precooked with commercial equipment. We, therefore, undertook to evaluate the effects of precooking under commercial conditions on palatability and cooking properties of patties containing various levels of soy protein. Different spice and soy levels were included in the design to simulate current school lunch/industry practices and provide a product that could vary in cooking and palatability traits.

Experimental

Seven ground beef formulations were prepared at two locations as outlined in Table 1. All raw materials were selected on the same days at each location. U.S. Utility square-cut chucks were used as the primary lean source; fat from U.S. Good and Choice plates was used to adjust the fat content. Minimum batch size of each formulation was 45 kg, and two batches of each formulation were prepared at both locations. Each batch was prepared from different chucks and plates.

Comminution:

Location A. All material was chopped in a commercial chopper for 1 min and sampled for fat analysis. After a 1-min mix, 10 grab samples (0.60 kg. each) were analyzed for fat with the Anyl-ray instrument. Fat content ranged between 28.5 to 29.7% for two batches, and the formulation was mixed for 1 min. Hydrated soy flour (1.5 water to 1 soy) and soy protein concentrate (see Table 1) were added to the formulation, and the batch was mixed again for 1 min. The product was passed through a 0.32-cm plate for the final grind. The ground beef mixture was formed into 75g patties with a formax patty machine. The patties were chilled with CO₂ to an internal temperature of about 0 to 2°C. They were then either frozen or precooked.

Location B. All raw material was passed through a 1.90-cm breaker plate, mixed for 1 min. and sampled for fat analysis. Fat content was determined with a Honeywell fat analyzer. Fat content was 28.5 to 29.5%, respectively, for the two batches.

Precooked Beef Patties

4

1 The mixtures were formulated and the patties prepared as described
2 for location A.

3 Precooking Methods

4 Location A. Patties were broiled in a custom-made gas broiler
5 to an internal temperature of approximately 50 to 55°C. The design
6 of the cooking apparatus was such that the patty moved along a belt
7 and was heated from both sides. The time from beginning of cooking
8 until the product reached the freezer was approximately 4 min.

9 Patties then passed through a liquid nitrogen tunnel for 5 to 6 min
10 and were chilled to an internal temperature of about -5°C.

11 Location B. Patties were broiled in a custom-made gas broiler
12 to an internal temperature of approximately 50 to 55°C. The heat
13 source was from both directions as in location A. The oven was
14 13 m long and the time from beginning of cooking until the product
15 reached the freezer was approximately 4 min. Patties were frozen
16 in a NH₃ carousel to an internal temperature of approximately -10°C.

17 Frozen patties from each location (raw and precooked) were
18 stored at -10°C for two days until shipment via air (-10°C) to the
19 Meat Science Research Laboratory at Beltsville, Maryland, where
20 they were stored at -20°C for analysis.

21 Cooking Losses

22 Fifty raw patties from each batch/formulation/location
23 combination were randomly selected for weighing before and after
24 the precooking/freezing treatment. Patties were weighed to the

1 nearest 28.0g. The weights of 15 raw, frozen patties and 15 precooked,
2 frozen patties were determined; each was reweighed after cooking at
3 the Meat Science Research Laboratory, and total cooking losses
4 were determined.

5 Cooking Procedures

6 Frozen raw and frozen precooked patties were cooked in an
7 electric oven preheated for 30 min at 225°C. Patties were placed
8 four to a pan, two pans per oven, and roasted at 200°C for 13 min.
9 The patties were not turned during cooking. Preliminary cooking
10 trials revealed that frozen patties whether precooked or raw,
11 required approximately the same amount of time to reach an internal
12 temperature of 55°C. Internal temperature was measured with iron/
13 constantan thermocouples connected to a Honeywell recorder.

14 Frozen, precooked patties were also cooked in a General Electric
15 model 500 microwave oven. Four patties were placed on a glass plate
16 and cooked for 2 min. Then the plate was rotated one-quarter turn
17 and the patties were cooked 2 more min.

18 Sample Preparation and Presentation to Panel

19 Samples were served warm to the panelists (within 2 min after
20 removing from the oven). Each patty was quartered, and two pieces from each
21 sample randomly allotted to each panelist. Samples were placed in nonwaxed
22 paper cups and served to the panelist one cup at a time. To prevent cooling
23 during serving, the paper cups were placed on heated sand for
24 no more than 2 to 3 min. Panelists were served distilled water
25 at room temperature so that they could rinse their mouths between
26 samples.

Trained Descriptive Attribute Panel

An eight-member panel, trained according to Cross et al. (1978), evaluated samples from each of the three cooking treatments in a total of 24 sessions; and six samples were evaluated at each session. The trained panel evaluated each sample for tenderness, fragmentation, juiciness, detectable connective tissue, and flavor intensity on the basis that 8 = extremely tender, juicy, no connective tissue, and intense flavor; and 1 = extremely tough, dry, an abundant amount of connective tissue, and bland flavor. The panel also subjectively evaluated the samples for flavor acceptability in order to detect those samples that were intense but unacceptable in flavor from those with intense acceptable flavor. Only four of the seven formulations (Table 1) were presented to the sensory panel.

Instron Shear

Ten patties from each treatment were sheared with single blade device attached to the Instron as described by Cross et al. (1978). Each patty was allowed to cool 2 hr and sectioned into four 2.54-cm squares. Each square was sheared once.

Oxidative Rancidity

Five patties from each treatment were randomly selected, frozen in liquid nitrogen, and powdered in a high-speed blender. Rancidity, as TBA values, was determined by the procedures of Tarladgis et al. (1964).

Statistical Analysis

The experimental design was a 4x3x2 factorial with incomplete blocks (formulation; cooking method and location) and each contrast (comparison) was estimatable in at least two of the six replications. Mean separation was performed according to Scheffe (1959). In designing the study, we were concerned that the precooking location interactions might confound the reheating methods location interactions. If location is found to have significant effects, all location interactions will vary accordingly; however, cooking method and formulation can still be studied if they are averaged over location. Consequently, when an interaction involving location was significant at the $P < 0.05$ level, we constructed a second ANOVA table (not shown) such that each sum of squares involving location was pooled with the error sum of squares into a residual sum of squares term. This enabled us to test the remaining mean squares and to gain information about main effects averaged over location. The estimate of pure error from the first ANOVA table (not shown) was used in each means analysis only when all interactions were nonsignificant ($P < 0.05$); otherwise, the pooled residual mean square from the second ANOVA table was used.

Results and Discussion

Mean squares associated with the main effects of formulation (except for juiciness) and cooking method were highly significant and quite large compared to each significant interaction mean square (data not shown). Consequently, real differences in formulation and/or cooking methods could be expected. This was confirmed with the second ANOVA (data not shown), which also showed no significant interactions between formulation and cooking method.

1 Sensory panel and Instron maximum shear force results are
2 presented in Tables 2 through 8. Mean separation was calculated
3 across all formulations and the three cooking methods. Mean
4 values for tenderness are presented in Table 2. The addition of
5 soy to the formulation significantly increased the panel ratings
6 for tenderness. The all-beef formulation (no soy proteins) was
7 rated "slightly tough" by the panel. Experience indicates that a
8 rating of less than 5 (8-point scale) by a trained panel usually
9 indicates that the product would be rated as "unacceptable" by a
10 consumer panel. Cross et al. (1976b), Huffman and Powell (1970)
11 and Twigg et al. (1975) have also reported increased tenderness with
12 increasing levels of soy. U.S. Utility chuck is a common raw
13 material for use in ground beef -- including that accepted by
14 U.S.D.A. school lunch purchase programs. Cross et al. (1976a)
15 reported that ground meat produced from U.S. Utility or lower
16 grade meat was unacceptably tough, due primarily to large amounts
17 of "tough" connective tissue. Likely, the addition of soy protein
18 diluted the connective tissue in the final product. Although
19 panel tenderness ratings for patties prepared at location A were
20 higher, formulations were ranked in the same order at each
21 location.

22 Patties that were cooked from the frozen, raw state were signifi-
23 cantly more tender than patties that were precooked and then reheated.
24 The differences were large enough to be important. Differences
25 between cooking methods were also significant within each formulation.

Mean values for Instron maximum shear force by formulation, cooking method, and location are presented in Table 3. There was a significant formulation/cooking method interaction but in view of the highly significant effect of cooking method, we concluded that differences exist between cooking methods. Panel and maximum shear force evaluations of tenderness agreed closely. All beef (no soy protein) patties were significantly ($P < 0.05$) tougher than patties containing high levels of soy protein. Precooked patties were significantly tougher than patties cooked from the raw state.

Panel ratings for ease of fragmentation (Table 4) followed trends similar to panel evaluations of tenderness (Table 2) and maximum shear force (Table 3). As it did for tenderness, the addition of soy protein increased the ratings for ease of fragmentation. Precooking with subsequent reheating adversely affected texture. Patties that were reheated with the microwave oven were rated significantly lower than were those cooked by the other two methods.

Panel ratings for connective tissue are presented in Table 5. The addition of soy protein to the formulation tended to offset the adverse effects of connective tissue. Cross et al. (1977) reported that the addition of mechanically deboned beef had a similar effect on ground beef produced from U.S. Utility grade meat. Cooking method significantly affected panel ratings for connective tissue. Patties cooked from the raw, frozen state had less panel-detectable connective tissue than reheated patties.

The addition of soy protein to the formulation did not significantly affect panel ratings for juiciness (Table 6) but cooking method had a

1 pronounced effect. Precooked, reheated patties were rated signifi-
2 cantly lower than patties cooked from the raw state, and the
3 differences were large enough to be of practical concern. There
4 were differences between locations; but, as with previous palatability
5 attributes (Tables 2-5), the rankings were identical between
6 locations.

7 Tables 7 and 8 present data for panel ratings of flavor intensity
8 and flavor acceptability. Acceptability ratings are usually used only
9 with untrained consumer panels but were used in this study to "flag"
10 possible off-flavors. In general, the panel objected to the level
11 of pepper and spices in the formulations. Many panelists commented
12 that the flavor was not necessarily undesirable but just not that of
13 ground beef. This comment was reflected in the intensity ratings
14 which were all above 6.0 (Table 7). No trends could be established
15 with regard to soy, spice level, or formulation. An exception was
16 the all beef formulation (No. 1); it received the highest ratings
17 for intensity and the lowest for acceptability (Tables 7 and 8).
18 Formulation 1 was the only one containing salt and black pepper.
19 Huffman et al. (1978) reported that low levels of salt usually
20 enhanced the flavor of ground beef. Likely, the black pepper was
21 the main contributor to the unfavorable ratings; but to be certain,
22 additional research will be necessary. Cooking method significantly
23 affected ratings for flavor intensity but not for flavor
24 acceptability (Tables 7 and 8). As mentioned, the spice level was
25 likely so high that any differences due to cooking method were masked.

1 Mean ratings for degree of doneness are presented in Table 9.

2 The formulation x location x cooking method interaction was highly
3 significant ($P < 0.005$). After adjustment for location, the formulation
4 x cooking method interaction (data not shown) was also highly
5 significant ($P < 0.005$). Results for formulation and cooking method
6 were significant ($P < 0.05$); however, we do not know whether the
7 significance was due to the formulation x cooking method interaction
8 or real differences in formulation and/or cooking method. Patties
9 that were not precooked tended to be rated less well done than patties
10 that were precooked and reheated. Reheating by roasting or with
11 microwave seemed to have little effect on degree of doneness.

12 Mean TBA values by cooking method are presented in Table 10.

13 The formulation x location interaction was significant (data not shown).
14 We then determined whether the formulations differed significantly in
15 TBA values given the significant interaction. The F value for
16 formulation was significant ($P < 0.002$) and indicated that formulation
17 1 generally had higher TBA values than the remaining formulations.
18 Cooking method had no significant effect on TBA values. By the end
19 of 2 months storage, most patties had reached a level of oxidative
20 rancidity that could be normally detected by a trained panel.

21 One of the often cited advantages for precooking and reheating
22 frozen patties is reduced cooking loss as compared to that of non-
23 precooked patties. Cooking loss can best be evaluated on the basis
24 of the total loss from raw patty to the final cooked patty. Total
25 loss can be determined from Table 11, which presents the stepwise
26 losses. Cooking losses for patties that were precooked and reheated

1 were from 10 to 15 percentage points greater than those for the non-
2 precooked patties. As expected, cooking loss was the highest for the
3 all-beef patty.

4 Conclusions

5 The level of soy protein in the formulation and cooking method
6 significantly affected palatability. The primary objective of this
7 study was to evaluate the effects of precooking beef patties on
8 ultimate palatability. Various levels of soy protein in the formulation
9 were included in the experimental design only so that we could evaluate
10 the effects of cooking methods on patties widely different in palatability.
11 Patties that were precooked, frozen, and reheated were tougher and drier,
12 and lost more weight during processing than those not precooked. The
13 all-beef patty had unacceptably high TBA values regardless of location
14 or cooking method. Our study indicates that there is little
15 advantage to precooking beef patties.

EFFECT OF QUALITY GRADE AND CUT FORMULATION ON THE PALATABILITY OF GROUND BEEF PATTIES

ABSTRACT

Chucks and short plates were selected from 25 carcasses representing the middle third of each of five U.S. quality grades. Beef patties were prepared from chucks and short plates individually and in combination. Taste tests were conducted on the samples in order to study the effect of quality grade and cut formulation on palatability of the cooked product. Over the range of carcasses graded from Prime to Cutter, taste panel subjective evaluations of tenderness, connective tissue amount and overall acceptability decreased significantly. Patties from Prime, Choice and Good carcasses were rated as acceptable in all palatability traits (5.0 or above on a 9-point scale) whereas patties from Utility and Cutter grades were rated 4.0 or less in tenderness, connective tissue amount and overall acceptability. Differences in juiciness and flavor were not substantially affected by quality grade. Patties formulated from chucks were rated more desirable in tenderness, flavor, connective tissue amount and overall acceptability than patties from short plates or short plate-chuck combinations. Differences in palatability due to quality grade were larger than those due to cuts.

INTRODUCTION

SINCE 1970, the U.S. Department of Agriculture has purchased over 415 million pounds of ground beef for distribution to schools. This product was purchased under the Schedule AA-USDA Specification for Frozen Ground Beef. This specification requires that beef and calf be the only ingredients and these shall be derived from fresh chilled beef or calf carcasses, sides and/or cuts of the U.S. Utility grade or higher for beef and U.S. Standard or higher for calf. The specification also states that at least 50% of the total weight of the beef (or calf) shall be from any one or any combination of primal cuts (major) and the remaining 50% or less may be from any one or any combination of rough (minor) cuts. Limited research information is available as to the acceptability of ground beef from various U.S. quality grades and to the effect of major versus minor cuts on palatability. Fruin and Van Duyne (1961) reported palatability differences in ground beef prepared from chucks and rounds from U.S. Commercial or Standard carcasses. Quality grade had no significant effect on palatability whereas panelists preferred ground beef from chucks to that from rounds. Information is needed as to the effect of wide ranges in quality grade and various combinations of major and minor cuts on palatability of cooked ground beef. Perhaps beef of a lower U.S. quality grade could be utilized to produce acceptable ground beef. Likewise it may be possible to use a higher proportion of rough cuts in the formulation thus producing a more economical product. Therefore, the study objective was to determine how ground beef formulations of varying quality grades and cuts would affect cooked ground beef palatability.

EXPERIMENTAL

FIVE CARCASSES were selected to represent the middle third of each of five USDA quality grades (Prime, Choice, Good, Utility and Cutter).

Each carcass was selected from the previous day's slaughter. From each carcass one chuck and both short plates were removed, boned and shipped about 10 miles in a refrigerated truck to the commercial Research Laboratory. To meat of the Utility and Cutter grades enough subcutaneous and kidney fat from other carcasses of those grades was added to approximate 24% fat content in the ground beef.

Sixteen combinations of ground beef were prepared as outlined in Table 1. The lean and fat were ground through a 0.64 cm plate, mechanically mixed for 2 min and ground through a 0.32 cm plate for the final grind. Prior to the final grind, the mixture was sampled for fat analysis by the Modified-Babcock procedure. Fat content was standardized at $24 \pm 2\%$ by the addition of appropriate amounts of fat or lean. Fat content was controlled, as much as possible, since the aim of the project was to study the effect of differences in grade and cut on palatability. In preparing the major vs. minor cut combinations for treatments 11-16 (Table 1) each chuck and plate was ground separately through the 0.64 cm plate, combined in equal amounts of fat or lean from chucks and plates, mixed and finally ground through a 0.32 cm plate. The ground meat was formed into 75g patties 10 cm in diameter using a Holymatic Patty Machine. During processing, the product internal temperature did not exceed 10°C. All patties were placed in boxes (4.5 kg to a box), frozen in a blast freezer (-30°C), and shipped to Beltsville, Md., via air freight.

Cooking

Patties were roasted from the frozen state in a 200°C oven for 9 min, quartered, and served as hot as possible to the panelists. A subsample of 10 patties per treatment was cooked to obtain weights for drip, evaporative and total cooking loss.

Panel selection and training

Male and female panelists were selected from the scientific and ancillary staff of the Agricultural Research Center. Selection was based on assessments of repeatability on duplicate samples and consistency of

ratings in relation to the group. Triangle tests were conducted over a period of 3 wk (total = 15) and 16 panelists were selected on the basis of these data. After each training session, discussions were held with the panelists in order to achieve unanimity in the interpretation of the scoring system. Panelists evaluated the samples under red lights in booths. If each panelist had been present for every session, there would have been an equal number (9) of evaluations by each panelist on every ground beef sample combination. The "ideal" panel situation would have resulted in each sample combination receiving 144 evaluations. In actuality, panelist attendance was not perfect. Three panelists had fewer than 50 evaluations while the remaining 13 averaged 120 evaluations out of a possible 144. To avoid problems in statistical analysis created by a wide disparity between the number of evaluations made by the panelists, the data from those three members were eliminated.

A trained 13-member panel rated each patty for tenderness and juiciness by using a 9-point scale (9 = extremely tender or juicy and 1 = extremely tough or dry). Tenderness and juiciness were evaluated during the first 5–10 chews. The amount of connective tissue residue remaining at the end of mastication was rated by using a 9-point scale (9 = none and 1 = very abundant amount). Due to the study design, flavor was rated on the basis of "desirability" rather than "intensity." Since off-flavors might be rated as "intense" an "intensity" scoring system could not differentiate between "intense-desirable" and "intense-undesirable" flavors. The taste panel evaluations were conducted over a time span of eight 3-day periods. Panelists evaluated six ground beef samples each day so that during each three-day period all sixteen sample combinations were tested. In addition, two sample combinations were repeated during each session. The daily assignment of sample combinations was presented to the panel nine times during the course of the study.

Statistical techniques

Panel palatability evaluations are discrete in nature (i.e., integer valued from 1 to 9). Nonparametric statistical methods are the most appropriate type of statistical technique to use on taste panel data. These methods do not assume that the data have any specific type of distribution. In particular, nonparametric methods do not require that the data have a normal distribution. On the other hand, it is reasonable to assume that results of cooking loss analyses are normally distributed. That assumption, if not entirely true, is at least sufficiently true to be satisfactory for most practical applications.

Friedman's Test (1937) which was used to analyze the taste panel data, is analogous to the two-way analysis of variance procedure. It is used to test the null hypothesis that all combinations have the same mean effects against the alternative hypothesis, that the combination mean effects are not all equal. The method of McDonald and Thompson (1967) uses the rank sums computed from Friedman's Test for the nonparametric multiple comparison of the combination means. "Experimentwise error rates" are used rather than "significance levels" when discussing this multiple comparison procedure. The "experimentwise error rate" is defined as "the ratio of the number of experiments in which at least one difference between means is falsely declared significant to the total number of experiments conducted over a long period time."

RESULTS & DISCUSSION

RESULTS of Friedman's Test indicated that the mean effects of the 16 sample combinations were significantly different at the 5% level of significance for each of the five palatability characteristics. Table 2 shows the results of nonparametric multiple comparisons of the 16 sample combinations for all five palatability characteristics. The combinations are arranged in order of decreasing values of the rank sums, and their means followed approximately the same order.

The nonparametric multiple comparisons shown in Table 2 enable the use of statistical techniques to objectively investigate the "closeness" of the mean values of the individual sample combinations. Ground beef formulated from Prime or Choice carcasses was more acceptable in all palatability traits (except juiciness) than ground beef prepared from Utility or Cutter carcasses. If a taste panel rating of 5.0 or above is arbitrarily designated as acceptable and 4.9 and below is unacceptable in palatability, then ground beef prepared from Prime, Choice and Good chucks or Prime and Choice plates was rated as "acceptable" in all five taste panel traits. Ground

beef prepared from Good plates and Utility and Cutter chucks and plates was usually below 5.0 (unacceptable).

Lean and fat from Choice and Cutter chucks and plates were combined to determine whether the addition of Choice meat would offset the low palatability ratings of ground beef

from Cutter carcasses. The addition of Choice grade meat (C&Cu/CP) increased the palatability ratings in all five traits; however, all mean ratings remained below 5.0 except those for flavor and juiciness. Panelists rated tenderness and connective tissue amount lowest of all the palatability traits. Probably the amount of connective tissue from lower grade carcasses significantly influenced the rating for tenderness and overall acceptability. This hypothesis is supported by the magnitude of the simple correlation coefficients between tenderness and connective tissue amount ($r = 0.74$) and overall acceptability and connective tissue amount ($r = 0.71$).

For chuck, mean scores for all palatability traits, except juiciness, were similar for Prime, Choice and Good meat. Choice, however, consistently scored highest. In contrast, the palatability ratings for plates or any combination containing plates tended to steadily decrease as quality grade decreased.

Nonparametric multiple comparisons by overall grade for all five palatability characteristics are presented in Table 3. Except for juiciness, the panelists' evaluations coincide with our "a priori" knowledge of the palatability characteristics of quality grades; that is, the mean values for Prime and Choice were very similar and consistently higher than those for Utility and Cutter. The mean values for the Good grade were usually intermediate. Differences in mean values between grades were not as pronounced for juiciness as for other palatability traits. In general, however, these results tend to confirm that USDA quality grades provide meaningful assessments of the quality of ground beef as measured by the other four palatability characteristics. Palatability ratings for the amount of connective tissue were less than 4.0 for Utility and Cutter ground beef. Possibly that trait accounts for the low scores in overall acceptability.

Nonparametric multiple comparisons for cuts are presented in Table 4. Except for juiciness, the mean palatability values were consistently and significantly higher for chuck than for plate. The mean value for the combination was consistently lower than the mean values for chuck or plate (except for

flavor). Apparently the addition of chuck to the formulation did not offset the adverse palatability of the plate. Juiciness did not differ significantly between means of cuts. Analysis of variance for drip loss, evaporation loss and total loss (not shown in table) indicated that the mean values of the sixteen combinations were not significantly different.

CONCLUSIONS

DIFFERENCES in palatability of ground beef patties between grades were significant and large enough to be important. Ground beef from Prime and Choice carcasses was consistently rated higher than that from Utility and Cutter; Good grade ground beef was usually intermediate. Ground beef from chucks was rated higher in palatability, except for juiciness, than that from plates or chuck-plate combinations. Apparently the addition of chuck in equal proportion with plate was not sufficient to bring the "combination" palatability up to an "acceptable" level in the lower grades. These data support the USDA's regulations requiring minimum quality grades. Further work is needed to evaluate additional quality grade and cut combinations to determine the most economical formulation that would yield an acceptable product.

DESTRUCTION OF BACTERIA IN BEEF PATTIES BY COOKING^{1,2}

A. W. Kotula, C. M. Chesnut³, B. S. Emswiler and E. P. Young³

Agricultural Research Service⁴, U.S. Department of Agriculture, Beltsville, MD 20705

SUMMARY

The destruction of bacteria in beef patties during cooking was evaluated to define the number of microbes that might be ingested when patties were cooked to different degrees of doneness. Commercially fabricated, 85-g beef patties from three wholesale distributors were stored frozen at -45 C or refrigerated for 1, 5 and 12 days at 4 C to simulate normal and abused products. Patties were cooked at either 149, 177, 204 or 232 C for a total of 2 to 8 minutes. Viable coliform bacteria were reduced to minimum countable levels (less than 14/g) by cooking at 177 C for 1.5 min on each side. Psychrotrophic bacteria were no longer countable after the patties had been cooked for 4 min per side at any of the temperatures, whereas destruction of aerobic bacteria required heat treatment beyond 4 minutes. The incidence of *Escherichia coli* and *Staphylococcus aureus* was reduced by more than 50% by cooking the beef patties. Reduction of bacterial viability by heating was more readily accomplished in the 12-day patties than in the frozen or 1-day patties.

(Key Words: Bacteria, Beef Patties, Cooking, Destruction of Bacteria.)

INTRODUCTION

Bacterial contamination of steaks and roasts has usually been considered to be a surface phenomenon. During broiling, roasting or frying the heat of cooking destroys most or all viable surface bacteria. For ground beef patties and restructured steaks, however, the possible

survival of bacteria in the center of the patty must be considered.

Emswiler *et al.* (1976) cited literature which reported that ground beef may contain extensive bacterial populations. Mueller (1975) indicated that burgers from a vending machine had a mean total aerobic count of 3.1×10^5 /g, but the count was reduced to 4.0×10^4 /g by heating the burgers in a microwave oven. During subsequent testing she found that reheating the hamburgers by microwave did not reduce bacterial numbers markedly. Mueller, in further tests, indicated that the total aerobic count was 5.2×10^6 /g in raw market hamburgers and 5.6×10^4 /g in fried patties. Cooking conditions were not specified, but the two log reduction from 6 to 4 appeared to be of some importance. Buck *et al.* (1975) reported that raw patties should be cooked for 6 min on each side on a grill at 137 C to reduce total aerobic bacteria from $10^5 - 10^8$ /g to about 10^2 /g; reductions were similar in lactose fermenters and *Escherichia coli*.

Our objective was to determine the influence of time and temperature of grilling on the destruction of bacteria in commercially fabricated beef patties. With the continued interest in the wholesomeness of meat, importance is placed on defining the number of microbes that might be ingested when patties are cooked to varying degrees of doneness. This information may be of particular use to processors who make precooked patties, which may be subsequently abused and permit the growth of *Staphylococcus aureus*.

EXPERIMENTAL PROCEDURE

Fresh, 85-g beef patties were purchased from three wholesale distributors. The patties typically were fabricated of triangle beef (chuck, brisket, plate) from U.S. Good carcasses. The meat was boned and stored at ambient temperature (about 11 C) for 1.5 hr, then ground through a 2.54 cm breaker plate and a .32 cm

DESTRUCTION OF BACTERIA

TABLE 1. INTERNAL TEMPERATURE (°C) OF COOKED BEEF PATTIES^a

Griddle temperature (°C)	Cooking time ^b (min/side)							
	1.0	1.5	2.0	2.5	3.0	3.5	4.0	4.5
149	5.0	10.0	53.5	59.0	63.0	65.0	66.5	69.0
177	29.5	41.0	45.0	58.5	63.0	64.5	67.0	69.0
204	39.5	51.0	61.5	64.5	66.5	70.5	72.0	76.0
232	41.0	59.0	65.0	70.0	72.5	75.0	74.5	78.0

^aEach value is the mean of two observations.^bCooked from frozen state.

fine plate. One fourth of the patties were frozen and stored at -45 C until cooked. The remainder were stored at 4 C for 1, 5 or 12 days prior to cooking to increase microbial numbers and provide products with different microbial counts.

Beef patties were cooked in duplicate on a Hotpoint (230 watt) griddle at either 149, 177, 204 or 232 C as determined by a surface thermometer. Cooking times were 1.0, 1.5, 2.0, 2.5, 3.0, 3.5 or 4.0 min per side. Frozen patties were cooked unthawed and patties stored at 4 C were removed from refrigeration immediately before cooking. Internal temperatures of cooked patties are shown in table 1. A sterile Ridak Sanitary Paper Gasket (Boonville Manufacturing Corporation, Boonville, NY) was used to circumscribe a cross section of the center of each patty to aid in the removal of an 11-g

sample, which was excised with a sterile scalpel and forceps. Each sample from the cooked and raw control patties was blended with 99 ml sterile phosphate buffer in a sterile Mason jar for 2 minutes. Serial dilutions were treated by the procedures described in table 2 for enumerating coliform, total aerobic and psychrotrophic bacteria. We tested for *E. coli* and coagulase positive *Staphylococcus aureus*, but did not count them.

The data, as the logarithms of the mean bacterial counts, were treated by analysis of variance (Snedecor and Cochran, 1972) and the Duncan's Multiple Range Test (Duncan, 1955). To preclude analysis of data with zero values, .1 was added to bacterial counts/gram, before their conversion to logarithms. In tables, where actual bacterial numbers were presented, the .1 was removed from each value.

^aFor a given bacterial group, means within a block followed by the same letter are not significantly different ($P < .05$). Each mean is based on four values.

RESULTS AND DISCUSSION

Evaluation of the uncooked beef patties from the three distributors (table 3) showed some significant differences in coliform, aerobic and psychrotrophic bacteria among samples stored for the same time. In the few instances of significance ($P < .05$), the magnitude of the difference was usually less than one log and therefore was of questionable importance. Stor-

age of the patties at 4 C increased bacterial numbers with time, and coliform counts ranged from 10^3 to 10^6 ; aerobic counts from 10^5 to 10^7 ; and psychrotrophic bacterial counts from 10^4 to 10^8 . Patties were not stored longer than 12 days because such patties would not normally be presented to consumers.

Time and temperature of cooking consistently had the greatest influence on survival of all bacteria counted (table 4). Temperature \times time

**($P < .01$).

***($P < .001$).

Figure 1. Mean coliform bacteria per gram of beef patty after cooking.

and the interactions with days affected bacterial counts significantly ($P < .01$). Distributor, batch and interactions with these variables were not significant.

Viable coliforms were reduced to minimum detectable limits by increases in either temperature or time of cooking (figure 1). Heating patties by cooking at 149 C for 2.5 min per side or 177 C for 2 min or 204 C for 1.5 min was adequate for significant ($P < .05$) and relevant decreases in viable coliform bacteria. These data confirm the fact that coliforms are sensitive to heat and suggest that enteric pathogens (*i.e.*, *Salmonella*) also might be destroyed.

The shortest cooking procedure, 1 min per side at 149 C, reduced aerobic bacteria by about 1 log. As temperature and time of cooking were increased, bacterial numbers decreased so that patties cooked at 149 C for 4 min, 177 C for 3.5 min, 204 C for 3 min or more, or at 232 C for 2.5 min or more, contained fewer than 100 bacteria/g (figure 2).

Figure 2. Mean aerobic bacteria per gram of beef patty after cooking.

Figure 3. Mean psychrotrophic bacteria per gram of beef patty after cooking.

Buck *et al.* (1975) suggested that patties should be cooked 6 min at 163 C. Those researchers evaluated 100-g patties that measured 87 x 18 mm, whereas we evaluated commercial 85-g patties that measured 108 x 10 mm. Kotula and Rough (1975) reported that commercial 85-g beef patties cooked 4 min per side at 149 C were rated as "well done."

Psychrotrophic bacteria are almost as sensitive to heat as the coliform bacteria (figure 3). Patties cooked by heating at 149 C or 177 C for 4 min per side, or 204 C for 3.5 min, or 232 C for 3 min reduced the bacterial count to about the minimum countable limits. Even cooking patties 2.5 min per side at 177 C or higher effectively reduced counts by about five logs from the initial number in raw patties.

^aFor a given bacterial group, means within a column having the same letters are not significantly different ($P < .05$) according to Duncan's Multiple Range Test (1955).

^bEach mean is based on 168 values.

^cEach mean is based on eight values for well-done patties.

Additional research is needed to determine whether partially cooked meat products, such as the burgers evaluated by Mueller (1975), contain inordinately high numbers of enteric or spoilage bacteria prior to the partial cooking procedure. The influence of composition (fat, water or extenders) on survival of bacteria during cooking should also be evaluated.

The incidence of *E. coli* and *S. aureus* was reduced by more than 50% by cooking the beef patties (table 5). Contrary to expectations, cooking apparently destroyed *E. coli* and *S. aureus* more readily in the 12-day patties than in the frozen and 1-day patties. The response was similar for coliforms, total aerobes, and psychrotrophs (table 6). In each instance, bacterial counts were greatest in the 12-day patties, but the log reduction by cooking was so large, counts were lower for 12-day than for frozen or 1-day cooked patties.

Increasing the temperature or time of cooking effectively reduced counts of all bacterial species evaluated. Increase of temperature, however, may be the procedure of choice because it shortened cooking time. Minimum effective cooking time would be important to

fast food outlets, schools, armed forces and to any purveyor responsible for mass feeding.

SUMMARY

Beef patties containing hydrated textured soy protein (TSP) or soy concentrate (SC) at 20 or 30% levels were evaluated by a standard consumer panel and by family consumer panels. The standard 52-member panel which evaluated four patties without condiments at each session were able to discern some difference ($P < .05$) in tenderness, flavor, appearance, aroma, juiciness and overall acceptability. All-beef patties and patties containing 20% TSP were rated higher in flavor and overall acceptability than the other patties. One panel of 52 families earning over \$10,000 a year could not discern any differences among patties, prepared at home with condiments, in flavor, appearance, aroma and overall acceptability. They also rated all-beef patties less tender than most patties containing soy. Another panel of 52 families earning less than \$10,000 per year did not discern any differences among patties. Age of the consumer affected tenderness, juiciness and aroma scores, but sex apparently did not affect any scores. On the basis of acceptability, families earning less than \$10,000 per year should provide a good potential market for beef patties containing soy protein.

(Key Words: Beef Patties, Beef-Soy Patties, Consumer Acceptance, Beef Palatability.)

INTRODUCTION

Previous studies on acceptance of beef patties containing soy protein reported the palat-

ability and acceptability of samples, which were cooked uniformly and presented to consumer panelists for evaluation under standard taste panel procedures. Glover (1968), Huffman and Powell (1970), Cross *et al.* (1975) and Kotula *et al.* (1976) presented data from such studies, indicating that beef patties containing up to 20% hydrated textured soy protein would be acceptable to the consumer.

Cross *et al.* (1975) indicated that palatability rating of soy-beef patties for flavor, appearance and overall acceptance were significantly higher by male than by female panelists. They indicated that further research should be carried out to study possible differences in palatability scores due to panelists' age, social, ethnic and economic status. Such information would be important in selection of evaluation panels. Panelists chosen to represent a large segment of potential customers might aid in selecting market areas for the sale of beef patties containing soy protein.

The present study was carried out to determine the reactions of panelists to meat patties that they were allowed to prepare at home by their preferred methods. We also studied the effects of sex, age and economic status on the attitudes of panelists toward all-beef patties that had been extended with soy protein.

EXPERIMENTAL PROCEDURE

Four brands of textured soy protein (TSP) designated A, B, C, D and two brands of soy concentrate (SC) designated E, F were hydrated, 1 to 1.5 and 1 to 2.5 parts with water. The hydrated products were added to triangle beef (chuck, brisket, plate) at levels of 20 and 30% by weight. All patties were produced commercially and fat content was 20%. The beef was ground through a 2.54 cm breaker plate, mixed with the hydrated soy product, ground through a 3.2 mm plate, formed into 85-g patties, which were boxed, frozen at -23°C and stored 6 months at -18°C prior to

¹Mr. E. James Koch provided guidance and assistance with the statistical analysis of the data. The Esskay Meat Packing Company provided facilities; Archer Daniels Midland Company, Cargill Inc., Pfizer Inc., Swift and Company and Central Soya, Inc. provided soy protein samples and technical assistance in patty fabrication. This study was funded in part by the U.S. Army Natick Research and Development Command.

^bTSP - Textured soy protein; SC - Soy concentrate.

evaluation.

Three consumer panels evaluated the patties. The experimental design was basically a balanced, incomplete block design for 13 treatments with four treatments in an incomplete block and four replications of the treatments in the design. The basic design was used eight times in the standard panel and four times in the family panel. The standard panel consisted of 52 members of ages 18 to 60 years; 13 females and 39 males. They each evaluated four quartered patties without condiments on each of two occasions. Patties provided were cooked on a grill at 177 °C for 3 min on each side. The second and third panels consisted of 52 families each with average annual incomes greater or less than \$10,000, respectively. The first 52 families in each income level to volunteer were accepted. Families were asked to rate a different patty type each week for 4 weeks. Thus each type of the 13 patties was evaluated by four families each week; by 16 families in 4 weeks. Families were instructed to prepare the patties in any manner desired. Patties and scoring sheets were provided for every member of the family, but only data from members older than 9 were used. Age and sex of all panelists were recorded. Panelists' scores were based on a 9-point scale, 1 for the poorest and 9 for the best. Descriptive terms for scoring codes for tenderness were: 1 — extremely tough; 2 — Very tough; 3 — Moderately tough; 4 — Slightly tough; 5 — Slightly tender; 6 — Moderately tender; 7 — Tender; 8 — Very tender; 9 — Extremely tender. Overall acceptability was rated on a 9-point scale wherein a rating of 1 was described by "I would eat this if forced to"; 3 by "I would hardly ever eat this"; 6 by "I like this and would eat it now and then"; and 9 by "I would eat this every opportunity I had."

RESULTS AND DISCUSSION

The standard panel discerned some significant differences among patties for each palatability trait evaluated (table 1). The all-beef patties were usually rated "slightly tough" and were less tender ($P < .05$) than patties containing TSP. Tenderness was about equal for patties containing SC and for all-beef patties. Flavor was rated as slightly desirable for all-beef patties and equal to patties containing 20% TSP and higher than any other patties ($P < .05$). In flavor, patties containing 30% SC were rated in

TABLE 4. EFFECT OF AGE AND SEX OF PANELISTS ON MEAN SCORES FOR PALATABILITY OF ALL PATTIES^a

Age group	(N)	Tenderness	Flavor	Appearance	Aroma	Juiciness	Overall acceptability
9 — 19	(385)	5.2 ± .02 ^b	5.8 ± .02	5.9 ± .02	5.4 ± .02	6.3 ± .02	5.4 ± .03

^aBased on data from a home panel of 52 families, each earning more than \$10,000 annually. Scores were based on a 9-point scale, 1 = poorest, 9 = best.

^bSE = Standard error of the mean.

the slightly to moderately undesirable range. In appearance, the 30% SC patties were rated slightly undesirable and lower ($P<.05$) than any others except product D of 30% TSP. The aroma of patties with 30% SC was rated slightly undesirable and lower ($P<.05$) than either the all-beef or patties containing TSP. All-beef patties were rated slightly juicy and lower than some of the patties with TSP, but higher ($P<.05$) than the SC product F, which rated slightly dry. In overall acceptability, all-beef patties and some of the patties containing TSP, which scored about 5.5, were described by the phrase "I would eat this now and then." The use of SC at either level reduced the overall acceptability ($P<.05$) to a score a little lower than that described by "I don't like this but would eat it on occasion."

Contrary to the ratings of the standard panel, the panel of families earning over \$10,000 a year could not discern any differences among the patties in flavor, appearance, aroma and overall acceptability (table 2). They agreed with the standard panel in rating the all-beef patties less tender than most of the patties containing TSP at either concentration. The family panel did not detect a significant difference in juiciness between all-beef patties and the others, but classified patties with SC product F as less juicy ($P<.05$) than some of the patties containing TSP.

The third panel (families earning less than \$10,000) did not detect any significant differences among the products and scores most palatability traits with a mean about 6. Juiciness which was scored the lowest had a mean score of 5.9. Responses to questions indicated that families in both panels prepared patties by similar methods; possibly families in the third panel had been conditioned to accept extended ground beef.

Mean scores for the three panels are compared in table 3. Except for three instances, the standard panel rated palatability traits lower than either of the other two panels. In every instance, the family panel earning less than \$10,000 rated the palatability traits higher ($P<.05$) than the other two panels. These data indicate that the standard panel effectively discerned differences in the palatability of the beef patties and the family consumer panels effectively determined the importance of those

differences to the public.

Age of the panelists apparently affected tenderness, juiciness, and aroma scores (table 4). Panelists over 50 scored tenderness more leniently than children of 9 to 19 years. Conversely, children were concerned less with juiciness than were people over 30. People over 30 tended to be less critical of aroma than the younger groups; flavor, appearance and overall acceptability were rated about the same by panelists regardless of age. We thought that panelists over 40 might have found difficulty in discerning flavor, due to loss of taste acuity, but age was not a factor in flavor discrimination.

Contrary to the report by Cross *et al.* (1975), sex did not influence palatability scores of the families earning more than \$10,000. The difference was attributed to the types of panels involved. Possibly when patties were cooked by the families' preferred methods, some of the discrete differences among samples and panelists disappeared. Furthermore, types of samples were not compared simultaneously in the home panels because each member of the family panels gave a general opinion about one product each week.

Although type, brand and concentration affected acceptability of soy protein in beef patties, age and sex of the consumer were not major factors in overall acceptability; and probably would not influence the sale of beef patties containing soy protein. The product was most readily accepted by the panel of families who earned less than \$10,000 per year, and these are the people who might best benefit from protein extenders.

STABILITY OF FROZEN GROUND BEEF CONTAINING MECHANICALLY DEBONED BEEF

ABSTRACT

Ground beef formulations containing three levels of mechanically deboned beef (MDB, 0, 10, and 20%) were stored at -12 , -18 and -23°C . Initially and at 2-wk intervals for 24 wk, one chub pack from each formulation and each storage temperature was removed for chemical and sensory analysis. Formulation (level of MDB) and storage time had significant effects on all palatability traits. Frozen storage temperature had no significant effect on any of the palatability traits. Interactions between temperature and time; formulation and time; and formulation and temperature were nonsignificant. There was no evidence that the formulations containing MDB affected the storage properties of ground beef any more so than ground beef containing 0% MDB.

INTRODUCTION

NEARLY ONE BILLION additional pounds of meat per year could be added to the nation's food supply through a process called "mechanically deboning" (Fried, 1976). This protein is wasted as a human food source. On September 10, 1976, a U.S. District court judge halted the use of mechanically deboned meat for human consumption. This injunction stopped USDA from enforcing interim regulations permitting the use of mechanically deboned meat. The injunction did not affect the USDA proposal for the use of mechanically deboned meat (USDA, 1976) but aroused public interest in the safety of this new product. In addition to the interest in the safety of MDM, considerable concern has been expressed by industry and consumers about the palatability, nutritional quality and storage stability of MDM.

Field et al. (1974); Cross et al. (1976); and Meiburg et al. (1976) reported that products of acceptable palatability and nutritional content could be produced from mechanically deboned meat. However, Goldstrand (1975); Lee et al. (1975); Meiberg et al. (1976); and Mello et al. (1976) indicated that some types of mechanically deboned meat could develop oxidative rancidity during storage. Little or no research data are available to indicate the storage stability of ground beef containing MDB; therefore, the objectives of this study were to evaluate the effects of storage time, storage temperature and level of mechanically deboned beef (MDB) on the rate of development of oxidative rancidity and on the palatability of frozen ground beef.

EXPERIMENTAL

Meat preparation

Ground beef formulations containing three levels of mechanically deboned beef (0, 10 and 20%) were from the same batches prepared for the palatability study reported by Cross et al. (1977). Raw meat materials were from USDA Utility triangles (chuck, foreshank, brisket and plate) and USDA Choice plates that were fabricated under the schedule AA USDA Regulations (1973). Coarse ground samples were randomly selected throughout the daily production (65,000 kg) until a weight of a sufficient quantity for formulating the treatments was obtained.

All hand boned meat was ground through a 1.90 cm plate with a Weiler grinder. Mechanically deboned beef (MDB) was obtained from necks, backs, ribs and pelvic girdle of USDA Utility carcasses that had been manually boned. These bones were passed through a Weiler bone

cutter into a Model AU 4171 Beehive Boning Machine equipped with a cylinder having 0.46 mm diameter holes. Deboned meat was boxed, quick frozen and stored at -34°C for subsequent analysis and product formulation. Prior to formulation, the MDB was ground through a 1.90 cm plate with a Weiler grinder and stored at -20°C . Coarse ground portions of beef and MDB were mixed for 3–4 min in a Chemetron mixer. During mixing, CO_2 snow was injected twice in order to maintain an internal temperature of 7°C or less. Following mixing, three samples were randomly obtained for fat analysis using the Hobart fat testing apparatus. Additional fat or lean was added from USDA Choice plates to adjust the fat content to approximately 23%. After mixing, the individual batches were ground through a 0.32 cm plate using a Weiler grinder. During processing the product internal temperature did not exceed 7°C . The product from each treatment was stuffed into 1 kg Cryovac Keeper Casings via a VeMag Pump (Model 43). The chub packs were boxed separately and placed in a -45°C blast freezer for 48 hr and subsequently sorted at -30°C until shipment. The frozen product was shipped to Beltsville, MD, via truck at -20°C .

Storage treatments

Ground beef chub packs from each treatment (0, 10 and 20%) were stored at -12 , -18 and -23°C . Initially and at 2-wk intervals, one chub pack from each formulation and each storage temperature was removed for subsequent thiobarbituric acid (TBA) and sensory analysis. Each chub pack was thawed at $2-3^{\circ}\text{C}$ for 24 hr and formed into 113g patties 0.95 cm in thickness with a Holymatic Model 200 patty machine. Patties were refrozen at -30°C for 6 hr and were cooked from the frozen state.

Rancidity

For TBA determination, two patties from each treatment were randomly selected, frozen in liquid nitrogen and powdered in a high speed blender. Rancidity, as TBA values, was determined by the procedures of Tarladgis et al. (1960).

Cooking

Frozen patties were broiled 14 min (7 min on each side) on a Farberware (model 450) electric grill to a "medium" degree of doneness (photographic color scale).

Sensory panel evaluations

Cooked patties were evaluated by a trained panel. Procedures for selection and training of the panel are described by Cross et al. (1978). The seven panelists rated patties from each formulation for differences in tenderness and juiciness on a 8-point rating scale (8 = extremely tender or juicy and 1 = extremely tough or dry). The amount of connective tissue residue remaining at the end of mastication was rated on an 8-point scale (8 = none and 1 = abundant amount). The panel was trained to evaluate differences in tenderness, juiciness and amount of connective tissue. The panel also subjectively evaluated the samples for desirability of appearance, aroma, flavor and for overall desirability (8 = extremely desirable and 1 = extremely undesirable). The entire study consisted of twelve 3-day taste sessions over a period of 6 months (36 sessions total). Four samples were presented to the panel at each session.

Statistical analysis

Data for each sensory variable was treated by analysis of variance (ANOVA) to test the effects of MDB level, storage temperature, storage time and some of the important interactions. With the taste panel responses as a vector, a multivariate analysis of variance was also performed (Press, 1971).

RESULTS & DISCUSSION

ANOVA and subsequent F tests for level of MDB, storage temperature and storage time are summarized in Table 1. All

Table 1—Analysis of variance for taste panel palatability traits

MDB/temperature	NS	NS	NS	NS	NS	NS	NS
Temperature/time	NS	NS	NS	NS	NS	*	NS

NS = nonsignificant

* $P < 0.05$ * $P < 0.01$

palatability traits were significantly ($P < 0.01$ or $P < 0.05$) affected by MDB level and storage time but not by frozen storage temperature. Among main effects only the interaction temperature by time for aroma was significant.

Results of the multivariate analysis corresponding to the MANOVA in Table 1 appear in Table 2. The multivariate analysis confirmed that MDB level and storage time were the most important main effects. The fact that there was no significant interaction between MDB level and time in the multivariate analysis of variance indicated that the beef patties deteriorated with time at the same rate for each treatment (MDB level).

Table 2—Multivariate analysis of variance (taste panel traits combined)

Source	Significance of F-ratios

NS = nonsignificant

* Significant at the $P < 0.01$ level of probabilityFig. 1—A linear function in terms of time for MDB level and tenderness (Significant at $P < 0.05$).

Therefore, for each palatability trait, only one equation, containing an intercept correction for each treatment, is needed to relate time to quality. The equation in its three forms, one for each MDB level, and the associated R^2 's are given in Figures 1–7. For each palatability trait, three functions were plotted—one for each MDB level. Because there was no MDB level by time interaction for each palatability trait, the three lines have the same slope. The separations among the lines reflect the mean differences among MDB levels.

Generally, the panel ratings for tenderness increased with the level of MDB (Fig. 1). Figure 1 confirms the results of Cross et al. (1977) that ratings for tenderness increased with level of MDB and that ground beef containing MDB deteriorated at the same rate as ground beef containing no MDB. It is commonly accepted that data from trained panels do not always accurately predict levels of consumer acceptance or preference. Many researchers who have compared data between trained and consumer panels found that meat that was rated "slightly tough, dry," etc., by trained panelists was usually rated "slightly unacceptable" by consumers. On a 8-point scale that rating would correspond to less than 5. When, on the basis of that comparison, we assigned 5.0 as the minimum acceptable panel rating, samples with 0% MDB were "unacceptable" at about 14 wk whereas samples with 10% and 20% MDB were still acceptable at 24 wk.

The report of Cross et al. (1977) was confirmed in that juiciness ratings were not affected significantly by level of MDB (Fig. 2). Juiciness ratings decreased with time but were still above the "unacceptable" (less than 5.0) cutoff at 24 wk.

Fig. 2—A linear function in terms of time for MDB level and juiciness (Significant at $P < 0.05$).

Fig. 3—A linear function in terms of time for MDB level and flavor (Significant at $P < 0.05$).

Flavor ratings were lowest in the ground beef containing 20% MDB, whereas, rate of decline did not differ among the three levels. Ground beef containing 20% MDB reached the borderline in flavor acceptability after about 10 wk of storage (Fig. 3).

As reported by Cross et al. (1977) detectable connective tissue decreased with increased levels of MDB. The 0% MDB ground beef initially was "unacceptable" in amount of connective tissue (Fig. 4). Cross et al. (1976) reported that ground beef from U.S. Utility grade beef is unacceptable high in amount of connective tissue. Ground beef with 10% and 20% MDB was "acceptable" throughout the 24 wk of storage.

Level of MDB had no significant effects on appearance or aroma (Fig. 5 and 6). Mean panel ratings decreased with time for both traits but were about 5.0 after 24 wk. Addition of MDB did not affect the rate of decline for overall desirability with storage time (Fig. 7). Ground beef approached the 5.0 cutoff in about 13 wk for 20% MDB, in 16 wk for 0% MDB and in about 24 wk for 10% MDB.

Results of ANOVA for the effects of MDB level, storage temperature, and storage time on TBA values appear in Table 1. The main effects for MDB level and storage time were significant ($P < 0.01$), whereas the main effect for storage temperature was not. Interaction for MDB level by storage temperature was significant ($P < 0.01$). The significant effect of storage time on TBA was not described by a linear or

Fig. 4—A linear function in terms of time for MDB level and connective tissue (Significant at $P < 0.05$).

Fig. 5—A linear function in terms of time for MDB level and appearance (Significant at $P < 0.05$).

quadratic function and therefore, was treated as a block effect caused by some controlled factor. Because there was a significant MDB level by temperature interaction we used Scheffe's method for multiple comparisons for differences among the three levels for each storage temperature.

Temperature/time	NS

^a NS = nonsignificant** Significant at the $P < 0.01$ level of probability.

Mean TBA values at three storage temperatures and three levels of MDB appear in Table 4. Storage temperature effects are compared within each MDB level by the numerical superscripts in the rows; the MDB level effects are compared by the letter superscripts within the columns. For 0% MDB, TBA values increased as storage temperature decreased, but the difference was significant only at -23°C . For 10% MDB, TBA values were significantly higher at -18°C than at -12 or -23°C . For 20% MDB, TBA values were not significantly affected by storage temperature. These differences, although significant are likely of no practical importance.

At -12 and -18°C storage temperature, TBA values were significantly higher for 10% MDB, while 0% MDB at -23°C had the highest TBA values. It is questionable whether the magnitude of the differences in TBA values is great enough to be of practical importance. Usually, depending on the product, TBA values must exceed 1.0 before a trained panel could detect differences in flavor.

CONCLUSIONS

FROM OUR DATA pertaining to the storage properties of ground beef containing MDB we conclude:

1. Temperature of frozen storage had no significant effects on palatability traits.
2. Rates of deterioration for palatability traits were not affected by level of MDB.
3. Ground beef containing 20% MDB approached the flavor score we defined as unacceptable after 10 wk at sub-freezing temperatures; while ground beef with 10% or 0% MDB still had acceptable flavor scores after 24 wk.
4. Although some significant differences were shown among treatments, TBA values for all formulations were below the value corresponding to a level of oxidative rancidity that

Table 4—Mean TBA values at three storage temperature and three levels of MDB^a

Dye Reduction Method for Estimating Bacterial Counts in Ground Beef

B. S. EMSWILER,* A. W. KOTULA, C. M. CHESNUT, AND E. P. YOUNG¹

Meat Science Research Laboratory, Agricultural Research Service, Beltsville, Maryland 20705

Received for publication 5 December 1975

A dye reduction method was developed for estimating total aerobic and/or psychrotrophic bacterial counts in ground beef. The method is based on color changes in indicator disks placed on the meat surface.

The use of chemical indicators as agents for the determination of sanitary quality of milk is well known (3, 4, 8). Various redox indicators have also been used as rapid tests for assessing the bacteriological quality and/or predicting the shelf life of other foods, including maple sap (5, 6), red meats (1, 2, 9-11), poultry (12, 14), and eggs, seafood, and vegetables (7, 13).

The purpose of this study was to develop a simple chemical reduction method for estimating the level of microbial contamination in ground beef. Such a method would prove advantageous if a meat wholesaler, retailer, or consumer could estimate the bacterial content of a package of ground beef by visual observation of color changes in an indicator disk placed on the meat surface at the time the meat was packaged.

We used three redox indicators, methylene blue (MB; Difco), 2,3,5-triphenyltetrazolium chloride (TTC; Difco), and resazurin (RZ; Manufacturing Chemists, Norwood, Ohio). MB changes from blue to colorless upon reduction; TTC changes from colorless to red (triphenylformazan); and resazurin changes from blue to pink (resofurin) to colorless (hydroresofurin). Ten concentrations (0.0025, 0.005, 0.01, 0.02, 0.04, 0.08, 0.16, 0.32, 0.64, and 1.28%) of each indicator were tested. A preliminary study with plates seeded with a mixed culture and five bacterial isolates from ground beef showed that none of the above concentrations of any of the indicators gave measurable zones of inhibition of bacterial growth around the disks on the seeded plates.

The indicators were dissolved in distilled water and 0.1 ml of solution was placed on each Whatman no. 2 filter paper disk (1 cm in diameter). The disks were dried at room temperature overnight in the dark after which half of the disks were covered on one side with one drop

(Pasteur pipette) of sterile 2% agar. Initial relative intensity readings of all the disks (with and without agar) were then made on an Aminco Microphotometer (Travenol Laboratories, Inc., Silver Spring, Md.) with an Uniscan attachment having a 0.5-mm slit and the standard ultraviolet light source emitting maximum energy at 360 nm. The agar layers were added and initial relative intensity readings were recorded immediately before the disks were placed on the ground beef patties.

A total of 112 fresh 3-ounce (ca. 85 g) ground beef patties representing two different batches from each of two processors were used in this study. Two control patties from each of the four batches were evaluated for initial total aerobic and psychrotrophic bacterial counts the day after the patties were delivered from the processors. On the same day, five disks representing five different concentrations of a given redox indicator were lightly pressed with forceps onto each of 96 patties. The agar surfaces of the disks were placed adjacent to the patties. Metrical membranes (Gelman Instrument Co.; 13 mm in diameter; 0.45- μ m pore size) were placed between the ground beef patties and the disks without an agar layer. Thus, eight patties (two from each batch) were tested for each treatment (3 dyes \times 10 concentrations/5 concentrations per patty \times agar surface versus Metrical membrane). The purpose of the agar surfaces and the Metrical membranes was to minimize the absorption of meat juices by the indicator disks.

The patties were placed in individual plastic bags (Baggies sandwich bags) and stored at 5 C. The eight remaining patties served as 5-day and 12-day controls. Half of the patties were evaluated after 5 days of storage and the remaining half after 12 days for total aerobic and psychrotrophic bacterial counts and relative intensity readings of the disks. Serial dilutions of the bacteria from an 11-g core sample (4 cm in diameter) from the center of each patty were made in phosphate-buffered diluent and

¹ Permanent address: Department of Animal Science, University of Maryland, College Park, Md. 20742.

plated on plate count agar (Difco) in cluster dishes. Plates for total aerobic counts were incubated for 48 h at 35 C and plates for psychrotrophic bacterial counts were incubated for 10 days at 5 C.

Initial mean log counts of total aerobic and psychrotrophic bacteria in the ground beef patties were 5.68 and 5.91, respectively. Mean log counts after 5 days of storage were 6.38 (range 4.86 to 7.50) for total aerobes and 7.12 (range 5.86 to 7.88) for psychrotrophs. After 12 days of storage, the mean log counts of total aerobic and psychrotrophic bacteria were 7.86 (range 7.04 to 8.39) and 8.41 (range 7.67 to 8.76), respectively.

Table 1 presents the correlation coefficients for total aerobic bacterial counts and relative intensity readings of the indicator disks. Table 2 presents the same data for psychrotrophs. Indicator disks with Metrical membranes gave

better correlations with counts than the disks with agar surfaces. Differences in the thickness of the agar layer and in the amount of indicator absorbed from the disk by the agar caused variability in relative intensity readings among agar indicator disks. Reduction was better correlated to bacterial counts with MB than with TTC or RZ. MB disks (with membranes) at the concentration of 1.28% gave *r* values of 0.91 for total aerobic bacteria and 0.97 for psychrotrophic bacteria. A major disadvantage inherent in the use of TTC is that the reduced compound (triphenylformazan) is red which makes it difficult to determine whether color changes are due to reduction caused by bacterial metabolites or to the absorption of meat juices by the disk. Psychrotrophic bacterial counts were better correlated than total aerobic counts to reduction of the indicators, a fact which is not surprising since it is primarily the psychro-

trophic bacteria which produce metabolites at 5 C.

Table 3 presents the regression equations for predicting total aerobic and/or psychrotrophic bacterial counts in ground beef from relative intensity readings of the reduced indicator disks. The MB method was more acceptable than the TTC and RZ methods; however, equations are presented for the concentration of each indicator which produced the best results. The results of this study show that MB dye reduction can be used to predict bacterial counts in ground beef. Although the ground beef patties used in this study were evaluated after 5 and 12 days of refrigerated storage, the MB disk reduction method could be used to estimate the bacterial quality of ground beef stored for any given period of time. The relative intensity reading on a microphotometer requires only minutes, whereas plating, incubation, and counting procedures require 2 days for total aerobic bacteria and up to 10 days for psychrotrophic bacteria.

Although these data indicate that MB reduction is an effective, rapid method for estimating bacterial counts in ground beef, further evaluation would be required before this procedure could prove useful in a meat packing plant or a supermarket. Standards of MB color, each representing a particular bacterial level, might be developed for visual comparison with the MB indicator disk. Visual comparison would eliminate the requirement for an instrument, but would introduce subjective error. Also, further studies are necessary to determine the effect of meat storage time and temperature on the degree of reduction (color change) and to establish whether there are minimal bacterial levels below which the method loses accuracy.

We thank E. James Koch, Agricultural Research Service, for advice and assistance in analyzing the data.

Bacteriological Quality and Shelf Life of Ground Beef

B. S. EMSWILER,* C. J. PIERSON, AND A. W. KOTULA

Meat Science Research Laboratory, Agricultural Research Service, U. S. Department of Agriculture,
Beltsville, Maryland 20705

Received for publication 17 February 1976

The bacteriological quality of unfrozen raw ground beef was evaluated after 0, 3, 6, 9, 12, 15, and 18 days of storage at $29 \pm 1^\circ\text{F}$ ($-1.7 \pm 0.6^\circ\text{C}$). At the time of fabrication, all of the ground beef samples contained 10^6 or fewer total aerobic and psychrotrophic bacteria/g; 81% contained 100 or fewer coliforms/g; 94% contained 100 or fewer *Escherichia coli*/g; and all of the samples contained 100 or fewer coagulase-positive *Staphylococcus aureus* and *Clostridium perfringens*/g. Total aerobic and psychrotrophic bacteria increased by 1 log between 3 and 18 days of storage. Coliform and *E. coli* counts decreased during storage, whereas coagulase-positive *S. aureus* and *C. perfringens* counts did not change significantly. These data indicate that meat processors, wholesalers, and retailers could improve the bacteriological quality and prolong the shelf life of ground beef packaged in oxygen-impermeable film if the temperature of the product never exceeded $29 \pm 1^\circ\text{F}$ ($-1.7 \pm 0.6^\circ\text{C}$).

Ground beef provides a favorable environment for the growth of bacteria. Bacteria normally found on the meat surface are distributed throughout the entire product during the grinding and mixing processes used in fabrication of ground beef. The bacterial population in ground beef depends upon the bacteriological quality of the trimmings and cuts of beef that are ground, sanitation during fabrication, type of packaging, and time and temperature of storage.

During the past few years, there has been an increased interest on the part of governmental agencies toward establishing microbiological criteria or standards for various food products, including ground beef. Some states (e.g., Oregon), cities, and counties have developed standards or guidelines to be enforced at their levels, and federal agencies are also active in developing various criteria (R. W. Johnston, Meat Industry Res. Conf., Univ. of Chicago, Chicago, Ill., 20-21 March 1975). The Center for Disease Control (10) has reported that ground beef is infrequently involved in foodborne outbreaks, even though pathogens such as coagulase-positive staphylococci and *Clostridium perfringens* can be isolated. Goepfert and Kim (3) concluded that even if ground beef is abused or mishandled, the pathogens which are present cannot multiply because they cannot compete with spoilage organisms which are present. However, the Center for Disease Control (11) recently reported on an extensive outbreak of salmonellosis (*Salmonella newport*) from ham-

burger eaten raw or rare. Proponents of microbiological standards insist that standards would improve the quality of ground beef.

The present study was conducted to determine (i) the bacteriological quality of unfrozen ground beef produced by a federally inspected processor and (ii) the bacteriological quality and shelf life of the product after storage at $29 \pm 1^\circ\text{F}$ ($-1.7 \pm 0.6^\circ\text{C}$) for 3, 6, 9, 12, 15, and 18 days.

MATERIALS AND METHODS

The ground beef used in this study was fabricated commercially under federal inspection and supplied, unfrozen, in 3-pound (1,361-g) chub packs. The product was fabricated from chilled cow beef (rounds and chucks), chilled beef flanks, line trimmings, and frozen flaked cow beef. The meats were passed through a coarse grinder (6.35-mm plate), then mixed in proportions not to exceed 25% fat content. The product was then passed through a fine grinder (3.17-mm plate) and finally through a packaging machine which stuffed ground beef into oxygen-impermeable casings to make the 3-pound chub packs. The final product is usually held overnight at -1.1°C and shipped to retail stores the following day. However, the chub packs used in this study were transported (20 min) the same day they were fabricated to the Beltsville Agricultural Research Center, where they were stored at $-1.7 \pm 0.6^\circ\text{C}$ until they were analyzed.

Ground beef samples were taken from two different batches (early morning and midmorning) on each of 4 days (1 day every 2 weeks) at the meat processing plant. Two 11-g samples of ground beef from each of the eight batches were taken from the

INFLUENCE OF ADDED SOY PROTEIN ON ELECTROPHORETIC PATTERNS OF THE WATER-SOLUBLE PROTEINS OF COOKED BEEF PATTIES

ABSTRACT

Patties containing all beef, 20% or 30% of either textured soy protein (TSP) or concentrate (SC) were cooked for different time-temperature combinations that, for the all-beef patties, produced rare (58°C), medium rare (62°C), medium well (66°C) and well (68°C) done meat. Sodium dodecyl sulfate-acrylamide gel electrophoresis of the water extract of the cooked patties yielded eight bands of different intensities. The intensities of seven bands decreased significantly ($P < 0.001$) with increasing degree of meat doneness. Seven of the eight band intensities decreased significantly ($P < 0.001$) with the addition of soy protein. The intensity of the eight bands which were 20.4, 12.9, 10.9, 12.6, 8.6, 4.6, 135.4 and 60.0 for the cooked, all-beef patties were reduced to 9, 5.2, 0.6, 1.2, 4.4, 2.7, 24.4 and 2.1, respectively, for the patties containing 30% added SC. The denaturation of the soluble proteins was greater in patties containing SC than TSP, as indicated by reduction of intensity in seven of the eight bands. The change in cooking characteristics was probably due to co-denaturation of the soluble meat protein with the soy protein.

INTRODUCTION

WHEN THE COST of meat increased, supplementation of meat products with vegetable proteins, such as textured soy protein or soy concentrate, became an economic reality. The addition of soy protein to meat can be detected, in both raw and cooked products, by electrophoretic techniques (Lee et al. 1975, 1976).

The influence of cooking beef on the denaturation of proteins and on the resultant electrophoretic patterns has been studied. Fogg and Harrison (1975), who recognized the importance of internal endpoint temperature on palatability and acceptance of meat, studied the influence of two endpoints, 58°C and 45°C in semitendinosus muscle on the electrophoretic patterns of the sarcoplasmic proteins. They concluded that heating to 25°C decreased the number and intensity of the slowest migrating protein components of the sarcoplasmic fraction, and the effects were more pronounced at 45°C. Lee et al. (1974) demonstrated that cooking meat at degree increments from 65°C to 90°C caused a progressive weakening and disappearance of the electrophoretic bands until, at 90°C, only one, myoglobin, of the six original bands remained. Those authors reported that the disappearance of the bands was so precise in relation to temperature increase, that they recommended electrophoresis for determining the temperature to which meat had been cooked. They indicated that the procedure could be used to ensure that meat had been cooked to 69°C as a precaution against foot-and-mouth disease virus that might be found in imported meat.

We have investigated the influence of the addition of soy protein to beef on the denaturation of water-soluble proteins during cooking, as measured by changes in electrophoretic patterns, and the relation of those changes to internal endpoint temperature (apparent degree of doneness).

EXPERIMENTAL

Sample preparation

Textured soy protein (TSP) and soy concentrate (SC) were hydrated

1:1.5 and 1:2.5 with water respectively, as recommended by the School Lunch Program (USDA, 1971). The beef, 75/25 (lean to fat) plate, chuck and brisket from U.S. Good carcasses, was ground through a 2.54 cm plate. Hydrated soy proteins were added to the beef to levels of 20 and 30%. The mixtures were ground through a final 0.32 cm plate and automatically formed into 85g, 11 mm thick patties. All-beef patties (control) were prepared in a similar manner, without soy protein. The five types of patties were packaged in corrugated boxes lined with plastic, frozen at -25°C and stored at -17°C until evaluated.

Patties were cooked from the frozen state on a grill to doneness endpoints of rare (58°C—internal temperature of patty), medium rare (62°C), medium well (66°C) or well (68°C). Three time-temperature combinations were used to obtain each degree of doneness, as tabulated below. Patties were visually categorized as to degree of doneness.

Griddle temp (°C)	Doneness			
	Rare (min)	Med rare (min)	Med well (min)	Well done (min)
121	8	9	10	11
149	5	6	7	8
177	4	5	6	7

Three patties of each of the five types were cooked at each time-temperature, then cooled. Various time-temperature relationships were used for each degree of doneness to introduce variability in cooking methodology which might be encountered under normal circumstances. A 5–10g core sample of the center of each of the 180 cooked patties was homogenized, with an equal weight of water at 16,000 rpm for 2 min, centrifuged for 15 min at 16,000 × G and filtered through Whatman No. 1 paper. The filtrate was used for electrophoretic determination of soluble proteins.

Sodium dodecyl sulfate (SDS) acrylamide gel electrophoresis

The method of Lee et al. (1974) was used for electrophoresis, and times were 3–4 hr. The number, migration distance and density of the stained bands were measured with an Aminco Microphotometer. Relative densities were recorded as area under the peak produced by each band and expressed in tenths of a square centimeter.

Statistical analyses

The data were treated by analysis of variance (Snedecor and Cochran, 1972) and the Multiple Range Test (Duncan, 1955).

RESULTS & DISCUSSION

Denaturation of all-beef patties

Figure 1 shows the SDS-acrylamide electrophoretograms of the water-soluble proteins from uncooked beef, beef-soy patties and soy proteins. Figure 2 shows band intensities of all-beef patties cooked to four internal temperatures, 58°C, 62°C, 66°C and 68°C representing four degrees of doneness, rare, medium rare, medium well and well, respectively. The loss of intensity of the bands is similar but not as marked as that reported by Lee et al. (1974) for beef cooked to endpoints of 65–90°C. The mean electrophoretic band intensities of all-beef patties are reported in a later table (4). The intensity of band 7 (myoglobin), which Lee et al. (1974) reported to be

the most resistant to heat denaturation, was not significantly different for beef cooked to endpoints of 58–66°C.

Effect of griddle temperature on beef-soy patty band intensities

The electrophoretic patterns of cooked beef patties containing soy protein displayed eight distinct bands. Only band 7 was significantly influenced by griddle temperature (Table 1). The mean intensities of band 7 were 92.6, 75.6 and 70.0 for 60 patties cooked at 121, 149 and 177°C, respectively. Griddle temperatures of 149 and 177°C significantly decreased the intensity of band 7.

Influence of degree of doneness on intensities of protein bands

We evaluated only one brand each of TSP and SC. Processing techniques for TSP and SC vary among companies and

might influence electrophoretic bands because high processing temperatures would increase denaturation of protein.

The intensities of all eight bands from patties containing soy protein were influenced significantly ($P < 0.001$, for bands 1–7; $P < 0.05$, for band 8) by degree of doneness to which the patties were cooked (Table 1). Table 2 shows decreases of intensity of 86, 77, 82, 87, 81, 64, 51 and 27% for bands 1 through 8, respectively, as the beef-soy patties were heated from 58°C to 68°C. These data agree with those of Fogg and Harrison (1975) who reported a decrease in number and intensity of the protein components having the largest molecular weight (the components migrating the shortest distance) with increasing temperatures.

Effect of soy additives on band intensity

Kotula and Rough (1975) reported that under similar con-

ditions, endpoint temperatures were 1–2 degrees lower for ground beef containing added soy than for all-beef patties. They, Judge et al. (1974) and Anderson and Lind (1975) also reported that moisture and fat losses during cooking were affected by the soy additives. The addition of soy protein to beef patties significantly changed ($P < 0.001$) the electrophoretic patterns of the cooked patties (Table 1), and the intensity of seven bands was significantly ($P < 0.05$) reduced by either soy protein at both concentrations (Table 3). Band 5 did not follow the same pattern. The intensity of band 5 differed significantly between 30% SC and the all-beef samples, but not between the all-beef and any of the other samples.

For every band but 8 (Table 3), both levels of SC reduced intensities more than corresponding levels of TSP; some of those differences were significant ($P < 0.05$).

From our present data, we could not determine whether the reduction in band intensity associated with the addition of soy protein was due to increased loss of soluble protein with the cooking juices or to co-denaturation of the soy proteins with the beef proteins. Kotula and Rough (1975) stated "Beef-soy patties formulated with SC lost more weight during cooking than patties formulated with TSP but less than all-beef patties. Whereas, beef-soy patties formulated with TSP lost more fat and less moisture to cooking juices than all-beef patties, beef-soy patties with SC lost more moisture and less fat to the cooking juices than the all-beef patties." That relationship, suggests that more soluble proteins might have been lost with

the greater volume of cooking juices from the SC patties, than from the TSP patties. That hypothesis might explain why the bands were less intense for SC than for TSP patties. That hypothesis however, would not explain why band intensities were lower for TSP than for all-beef patties which lost more moisture during cooking, and thus should have had less dense bands.

To explain the denaturation of myoglobin at a lower temperature with than without the presence of other protein in solution, Bernofsky et al. (1959) hypothesized that myoglobin co-denatures with other water-soluble protein from meat. Such co-denaturation of the soluble meat proteins with the soluble soy proteins might explain the decrease in band intensity associated with the addition of soy protein to beef.

When TSP and SC were incorporated into beef patties which were then cooked to different degrees of doneness, band intensities were decreased by both temperature increase and the addition of soy protein (Fig. 3 and 4).

Data in Table 4 indicate that SDS acrylamide gel electrophoresis might be used for estimating the maximum temperature to which beef has been cooked, as reported by Lee et al. (1974), for beef when discrete temperature differences of only a few degrees are not important. The influence of SC on loss of intensity for bands 7 and 8 was greater for the rare patties than for the all-beef patties cooked to the "well" degree of doneness. Lee et al. (1974) suggested that, in their electro-

phoretic method, reduction of the number of distinct protein bands to four or less indicated that beef had been cooked to 70°C and thus ensured the inactivation of the foot-and-mouth disease virus. Figures 3 and 4 show electrophoretic patterns of beef-soy patties with fewer than four protein bands for the patties that had been cooked to endpoints ranging from 58–68°C. Thus the procedure of Lee et al. (1974), which apparently was effective for all-beef products in casings, should not be extrapolated for use with meat products to which other proteins such as soy have been added.

Effects should be determined of other potential meat additives (casein, whey, peanuts, cottonseed and water) on the electrophoretic patterns of the fabricated products during cooking.

holding bin between the fine grinder and the packaging machine, making a total of 16 production line (0-time) samples. The production line samples were analyzed in a mobile microbiology laboratory parked beside the meat plant. Eighteen chub packs were collected from each batch (total, 144 chub packs) for storage so that three chub packs from each batch were available for sampling after 3, 6, 9, 12, 15, and 18 days of storage at -1.7 ± 0.6 C.

The 11-g samples obtained before packaging (0-time) were blended 2 min in 99 ml of sterile phosphate-buffered diluent (pH 7). Three locations were sampled aseptically within each chub pack to obtain a 25-g sample that was blended 2 min in 225 ml of sterile phosphate-buffered diluent. Serial dilutions of the samples were plated in duplicate on plate count agar (Difco Laboratories, Detroit, Mich.) in cluster dishes. Plates for total aerobic bacterial counts were incubated 48 h at 35 C, and plates for psychrotrophic bacterial counts were incubated 10 days at 5 C.

Coliforms, *Escherichia coli*, and *Staphylococcus aureus* were enumerated according to the methods described in the Microbiology Laboratory Guidebook (12). All EC broth (Baltimore Biological Laboratory, Cockeysville, Md.) tubes showing gas after 24 h at 45.5 C were streaked onto Levine eosin methylene blue agar (BBL) for detection of typical *E. coli* colonies.

C. perfringens was isolated by inoculating one tube of neutral red cooked meat (NRCM) medium from each of the serial dilutions of the samples in phosphate buffer. Each tube of NRCM medium contained about 1.0 g of cooked meat medium (Difco) plus 8 ml of NRCM diluent (10.0 g of tryptone [Difco]; 1.0 g of sodium thioglycolate; 1.0 g of soluble starch [Difco]; 2.0 g of dextrose; 5 ml of a 1% solution of neutral red [Difco] dissolved in 60% ethanol; and 1 liter of distilled water). Presumptive positive tubes of NRCM were those that turned yellow after 24 h at 35 C. Any red tubes were held 3 days before they were recorded as negative. From each positive tube of NRCM, a tube of peptone colloid medium (Difco) was inoculated (1 ml) and incubated 24 h at 35 C. From each inoculated peptone colloid tube, a tube of Strong sporulation medium (4.0 g of yeast extract

[Difco]; 15.0 g of proteose peptone no. 3 [Difco]; 4.0 g of soluble starch [Difco]; 1.0 g of sodium thioglycolate; 10.0 g of Na_2HPO_4 ; 0.5 g of Norit A [J. T. Baker Chemical Co., Phillipsburg, N.J.]; and 1 liter of distilled water) was inoculated (1 ml) and incubated 24 h at 35 C. From each tube of previously inoculated Strong sporulation medium, 1 ml was then pipetted into tubes containing 1.0 ml filtered 100% ethanol. The alcohol tubes were shaken and left at room temperature for 1 to 2 h, then 0.1 ml of the alcohol mixture from each tube was pipetted onto plates of sulfite polymyxin sulfadiazine agar (SPS; Difco) containing 1.0 ml of ferric ammonium citrate solution (34.0 g of anhydrous sodium thiosulfate, 4.0 g of ferric ammonium citrate, and 100 ml of distilled water) per 100 ml of SPS agar. The plates were streaked for isolation, capped with an additional 5 to 7 ml of agar, and incubated in GasPak 100 anaerobic systems (BBL) for 48 h at 35 C. Two typical black colonies were picked from each SPS plate for confirmation tests. Each colony was used to inoculate a tube of indole-nitrite medium (BBL) and a tube of motility-nitrite medium (25 g of indole-nitrite medium, 2 g of agar, and 1 liter of distilled water). The tubes were incubated for 48 h at 35 C, then examined for motility, indole production (with Kovac reagent), and nitrate reduction (with sulfanilic acid reagent and α -naphthylamine reagent). Gram-positive rods which were nonmotile, indole negative, and nitrate positive were considered to be *C. perfringens*.

RESULTS

The bacterial contents of the raw ground beef before and after storage at -1.7 ± 0.6 C are summarized in Table 1. Initial mean \log_{10} counts for total aerobic and psychrotrophic bacteria in the ground beef samples were 4.60/g and 4.86/g, respectively. Total aerobic and psychrotrophic bacterial counts after 3 and 6 days of storage were significantly ($P \leq 0.05$) lower than the initial counts, but the magnitude of the differences was of questionable importance. However, the counts increased significantly ($P \leq 0.05$) after 9, 12, 15, and 18 days of storage.

TABLE 1. Mean \log_{10} counts^a of selected bacteria in raw ground beef stored at -1.7 ± 0.6 C

^a Values for storage day 0 are mean \log_{10} counts of 16 samples; all other values are mean \log_{10} counts of 24 samples.

^b Values in the same column followed by different letters are significantly ($P \leq 0.05$) different according to Duncan's multiple-range test (2).

There was a 1 log increase in total aerobes and psychrotrophs per gram of ground beef between 3 and 18 days of storage. The initial mean \log_{10} coliform count in the ground beef was 1.70/g. A significant ($P \leq 0.05$) reduction in the initial number of viable coliforms was evident after 6, 9, 12, 15, and 18 days of storage at -1.7 ± 0.6 C. Mean \log_{10} counts of *E. coli* decreased, although not significantly, from an initial count of 1.24/g to 1.04/g after 18 days of storage. Coagulase-positive *S. aureus* and *C. perfringens* counts did not change significantly during storage. Figure 1 depicts graphically the effects of storing ground beef at -1.7 ± 0.6 C on the viability of total aerobes, psychrotrophs, coliforms, *E. coli*, *S. aureus*, and *C. perfringens* present in the meat. The appearance and odor of the 18-day-old ground beef chub packs further indicated that they were edible.

The distributions of the bacterial counts in the ground beef samples are shown in Tables 2 and 3. At the time of manufacture, all of the ground beef samples had aerobic plate counts of 10^6 or fewer/g, and 94% of the samples contained 10^5 or fewer total aerobic bacteria/g. All of the samples had initial psychrotrophic bacterial counts of 10^6 or fewer/g, and 50% contained 10^5 or fewer psychrotrophs/g. Total aerobic and

FIG. 1. Effects of storage at -1.7 ± 0.6 C for 18 days on the microbiological quality of ground beef. Values for storage day 0 are mean \log_{10} counts of 16 samples; all other values are mean \log_{10} counts of 24 samples.

psychrotrophic bacterial counts did not exceed 10^6 /g until 18 days of storage, when 17% of the samples had total aerobic counts between 10^6 and 10^7 /g and 25% had psychrotrophic counts between 10^6 and 10^7 /g.

At the time of manufacture, 81% of the samples contained 100 or fewer coliforms/g; 94% contained 100 or fewer *E. coli*/g; and 100% contained 100 or fewer *S. aureus* and *C. perfringens*/g (Table 3). By the laboratory methods employed in this study, 19% of the samples contained less than 10 coliforms/g at the time of manufacture; 31% contained less than 10 *E. coli*/g; 50% contained less than 10 *S. aureus*/g; and 81% contained less than 10 *C. perfringens*/g. These counts either decreased or remained relatively unchanged throughout the storage period (Fig. 1).

DISCUSSION

The Oregon microbiological standards state that fresh or frozen meat products should not contain more than 5 million microorganisms/g or 50 *E. coli*/g (R. W. Johnston, Meat Industry Res. Conf., Univ. of Chicago, Chicago, Ill., 20-21 March 1975). None of the ground beef samples evaluated in this study exceeded the Oregon standard for total bacterial counts, even after 18 days of storage at -1.7 ± 0.6 C. However, 15% of the samples (seven production line samples and five 3-day, three 6-day, one 9-day, one 12-day, four 15-day, and three 18-day chub packs) exceeded 50 *E. coli*/g. The incidence and

^a Samples for each storage day represent eight batches (4 days \times two batches) of ground beef.

behavior of *E. coli*, *S. aureus* and *C. perfringens* in the ground beef used in this study were similar to those previously published (3,4). The increased interest in the establishment of microbiological standards for meat products suggests that the sources of those food-borne pathogens should be studied further to reduce their numbers in the ground beef supply.

Other investigators have reported that some raw ground beef collected at retail markets may have high bacterial counts. Rogers and McCleskey (7) found bacterial counts in excess of 10⁷/g in ground beef from 16 of 24 retail markets. Coliform counts varied widely among samples (20 to 1,100,000/g), and no marked correlation was noted between coliform and plate counts. Rao (6) reported that standard plate counts were 11,000 to 36,533,000/g and coliform counts were 233 to 71,333/g on 15

ground beef samples taken from a retail market. There was no relationship between coliform counts and plate counts. Law et al. (5) found that the bacterial population of 32 ground beef samples from 16 retail stores varied from 1.9×10^6 to 4.6×10^8 /g. Duitschaever et al. (1) reported that 64% of 213 retail ground beef samples had aerobic plate counts in excess of 10⁷/g and some in excess of 10⁸/g.

Surkiewicz et al. (8) conducted a bacteriological survey of raw beef patties collected from 42 federally inspected establishments. At the time of manufacture, 76% of 74 sets of raw beef patties had aerobic plate counts of 10⁶ or fewer/g; 84% contained 100 or fewer coliforms/g; 92% contained 100 or fewer *E. coli*/g; and 85% contained 100 or fewer *S. aureus*/g. Salmonellae were isolated from only 3 (0.4%) of 735 beef patties.

Our study showed that by use of proven sanitary practices ground beef of good bacteriological quality can be produced commercially. Modern advances in sanitation and refrigeration allow no excuse for high bacterial counts in ground beef offered to the consumer at the retail level. Ground beef is normally exposed to refrigerated temperatures of 35 to 40 F (1.67 to 4.44 C) during distribution and display. Such temperatures result in shorter generation times for psychrotrophic bacteria (9) than the temperature used in this study. Our data indicate that meat processors, wholesalers, and retailers could improve the bacteriological quality and prolong the shelf life of ground beef packaged in oxygen-impermeable film if the temperature of the product never exceeded -1.7 ± 0.6 C.

ACKNOWLEDGMENTS

We thank Safeway Stores, Inc., which supplied facilities and the ground beef, and E. James Koch, Agricultural Research Service, U. S. Department of Agriculture, for advice and assistance in analyzing the data.

EVALUATION OF BEEF PATTIES CONTAINING SOY PROTEIN, DURING 12-MONTH FROZEN STORAGE

ABSTRACT

Patties containing 20 or 30% of soy protein (textured or concentrate) were stored at -17°C and evaluated tri-monthly for 1 yr for effects of storage on organoleptic properties and chemical changes. Textured soy proteins from four manufacturers and concentrate from two manufacturers were tested. Fat content was about 20% for all patties. A 52-member panel of adults, from 18–60 yr of age, evaluated (without condiments) the 12 types of patties with soy and the all-meat patties. A 13-member panel evaluated the effects of condiments on acceptability. Chemical tests included proximate analysis (ash, fat, moisture and protein), pH, peroxide values and thiobarbituric acid (TBA) number. Mean scores for flavor, aroma and overall acceptability of the patties did not change significantly during the year of frozen storage. Some differences were significant in scores for tenderness, appearance and juiciness, but they were too small to be of practical importance. The addition of condiments to patties did not improve the scores for appearance and juiciness but did improve scores for flavor, aroma, tenderness and overall acceptability. Throughout the year, patties containing soy concentrate at either 20 or 30% rated significantly lower than most of the patties containing textured soy protein and the all-beef patties when evaluated for flavor, appearance, aroma and overall acceptability. Although compositional changes in patties were evident during 12 months of storage, their magnitudes were inconsequential. Peroxide and TBA values increased during storage at a faster rate for all-beef patties than for patties containing soy protein. Some panelists were able to detect old or rancid condition in some products during the 9- and 12-month storage but most palatability traits were not significantly different in patties that had been stored for up to 12 months. Soy protein additives tended to inhibit rancidity development.

INTRODUCTION

BEEF PATTIES are used extensively by the Armed Forces to provide high quality protein in a form that is generally acceptable to civilian and military personnel. In order for the Armed Forces to benefit from the addition of soy protein to meat, the resulting product has to be capable of withstanding 9-month frozen storage without adverse chemical or palatability changes. Huffman and Powell (1970) reported that patties containing 2% soy product were better than patties containing all-beef. Information has not been reported on acceptability of patties containing soy protein products at 20 or 30% levels after several months of frozen storage.

The objective of this research was to investigate the acceptability of beef patties containing soy protein to persons of military age. Interest was directed toward evaluation of patties containing added soy protein at levels that include present upper limits of addition for use by the School Lunch Program (Food and Nutrition Service Notice 219). The influence of condiments on the acceptability of cooked patties containing soy protein was also evaluated. A secondary objective was to investigate changes in moisture content, peroxide and TBA values during frozen storage of beef patties containing soy proteins. The chemical composition of soy protein and beef patties containing soy protein was also investigated.

EXPERIMENTAL

Patty fabrication

Twelve lots of 85g beef patties, six containing 20% and six containing 30% hydrated soy protein, were prepared at a commercial meat processing plant from textured vegetable protein from four manufacturers (A, B, C, D) and soy concentrates from two manufacturers (E, F). All soy proteins were dehydrated, vitamin enriched and contained no flavor additives, but they differed in physical appearance. Particle size ranged from 16–50 mesh for brand F to $2\frac{1}{2}$ –9 mesh for brand C. Beef patties (about 228.6 kg) containing hydrated soy protein were formulated for each lot according to recommendations of the USDA Food and Nutrition Service Notice 219: for the School Lunch Program (1971).

As a control, a 453.6 kg lot of all-beef (80% lean/20% fat) patties was prepared. Meat for producing all lots of beef patties was obtained from USDA Good Grade triangle beef (chuck, brisket, plate) in accordance with Military Specification Mil-B-003854F. In order to maintain fat content at approximately 20% in all patties, the beef for formulating patties at the 20% level of hydrated soy protein contained approximately 25% fat; whereas, meat used for fabricating patties having 30% hydrated soy protein, initially contained approximately 30% fat. The meat used for the all-beef patties contained 20.5% fat.

The specified quantity of meat for each lot, as listed above, was ground through a 2.54 cm plate. The Hobart fat tester and a chemical method of Bittenbender (1970) were both used for determination of fat in samples taken at random from each lot. Adjustments were made on the percentage of fat in each lot, by correcting with 50/50 trim, or 80/20 triangle, and fat determinations were again made to ensure proper fat content. Meat for all lots was stored overnight in coolers to maintain meat temperature at -2 to 0°C .

Hydration

All soy proteins were hydrated at least 10 min according to manufacturer's suggestions for their particular product with tap water (16°C). Proportion of water was 1.5:1 for textured soy protein and 2.5:1 for soy concentrate. Products C, D and F were hydrated in meat trucks for about 15 min in accordance with manufacturer's recommendations. Appropriate quantities of coarse ground meat and hydrated soy protein were alternately added to a mixer and blended for about 3 min. Products A, B and E were hydrated for 10 min in the mixer then meat was added and the ingredients mixed for 5 min.

Packaging and storage

Each lot of the meat-hydrated soy protein mixture was ground through a double screw 3.2 mm plate grinder, then carried on a conveyor to a Hollmatic patty machine which formed the mix into 85g patties.

The patties were packed into 47.6 cm \times 33 cm \times 16.2 cm boxes which met Military requirements for overseas shipment (Federal Specifications: PPP-B-636c and L-P-378c; and Military Standard-129E). Individual patties were separated by moisture vapor proof paper. A sheet of moisture vapor proof paper was placed on top of the stacks, and another 12 stacks of patties were added. The plastic liner was then folded back to cover those patties, and the boxes were sealed. Each box contained 168 patties with a net weight of 14.3 kg. All packed boxes were frozen in air blast at -25°C and stored about 3 days at -17°C until shipped to the laboratory for long term storage at -17°C as indicated in the experimental design.

^a Values within a column followed by the same letter or letters were not significantly different ($P < 0.05$) according to analysis of variance and Duncan's Multiple Range Test (1955). Each value is based on 32 determinations. Scores were based on a 9-point hedonic scale, 1 — poorest, 9 — best.

Organoleptic evaluation

Samples, selected randomly from each lot, were evaluated by a panel, composed of 52 adults at intervals of 0, 3, 6, 9 and 12 months. Patties were cooked from the frozen state on a Hotpoint (230 watt) griddle at 177°C for 3 min on each side. This time-temperature resulted in the degree of doneness at which the final pinkness at the center of the all-beef patties disappeared. The patties were removed from the griddle, quartered, randomly placed on a plate according to Plan 11.22 of Cochran and Cox (1957), and served to the panelists for evaluation. No condiments were added to the patties. Discussion of patties by panelists during evaluation was not permitted. Panelists evaluated each quarter for tenderness, flavor, appearance, aroma, juiciness, and overall acceptability.

A second panel of 13 USDA employees was convened. The specific objective of this panel was to determine the effect of condiments on taste panel evaluation of the patties. Consequently, patties were served on the first day without condiments as in the evening panels, while patties on the second day were cooked with monosodium glutamate, salt and pepper, and served on a bun with pickles, mustard and catsup; cola and potato chips were also given to the panelists. Cooking, sampling and evaluation procedures were the same as for the evening panel.

Chemical analysis of patties

Proximate analysis of patties from each lot was conducted after 0, 3, 6, 9 and 12 months storage. Samples, selected randomly, were homogenized in a blender for 2 min and prepared according to AOAC (23.001) (1965). Analyses were completed following AOAC procedures for moisture (23.003), ash (29.012), fat (23.005), protein (23.009), and peroxide value (26.024 and 26.025). In addition, the thiobarbituric acid test (TBA) for rancidity, was conducted by a distillation method of Tarladgis et al. (1960). The pH of patties blended in distilled water was determined with a Beckman Expandamatic pH Meter.

RESULTS & DISCUSSION

Organoleptic evaluation — 52-member panel

Patties without condiments. Flavor. Although all-beef patties had the highest average rating, scores for patties containing 20% textured protein were not significantly lower ($P < 0.05$).

^a Values within a column followed by the same letter or letters were not significantly different ($P < 0.05$) according to analysis of variance and Duncan's Multiple Range Test (1955). Each value is based on 32 determinations. Scores were based on a 9-point hedonic scale, 1 — poorest, 9 — best.

Scores for patties containing 30% soy protein were generally lower than corresponding patties with 20% soy additives, but the differences were not always significant. In many instances, patties containing soy concentrates were scored significantly lower ($P < 0.05$) than those containing textured proteins (Table 1).

Some panelists detected old or rancid flavor in the 9- and 12-month patties. Sessa (1974) found that phospholipids in soybeans such as phosphatidylcholine developed off-flavors when oxidized. The coefficient of correlation between TBA values and flavor scores was -0.63 , indicating that lipid oxidation might have contributed to flavor differences.

Overall, flavor was best in the all-beef patties, followed by patties containing textured soy protein at 20%, then 30%. Soy protein concentrate patties at 20% were still less flavorful and patties containing 30% soy protein concentrate were least flavorful. The differences in acceptability of flavor of the 13 types of patties appeared to be similar for all storage periods.

Appearance. Patties with 30% soy protein were generally scored lower than patties containing 20%, but the differences were only significant for concentrates (Table 2). Patties containing textured soy protein product D were rated consistently lower than the other patties with textured protein, and at the 30% level of addition to patties the difference was significant ($P < 0.05$). Patties with soy concentrates were significantly lower ($P < 0.05$) than patties with textured soy protein. Particle size, again, might be a factor in the lower scores for concentrates, which were finer and gave the patty a grainy appearance.

Aroma. Aroma of patties containing textured soy proteins varied little, even between 30% and 20% (Table 3). Patties containing concentrates usually scored lower in aroma than textured and all-beef patties. This difference was often significant ($P < 0.05$) when patties contained 30% concentrate. Patties with 20% concentrate sometimes scored significantly

lower ($P < 0.05$) in aroma than textured or all-beef patties.

Juiciness. Patties containing textured soy protein consistently appeared to be more juicy than the all-beef patties or the patties with concentrates. Differences between all-beef and soy concentrate patties, though sometimes significant, were not of sufficient magnitude to be meaningful (Table 4).

Tenderness. Patties with 30% textured protein, then 20%, had the highest scores, followed by concentrates at 30% then 20% (Table 5). All-beef patties had the lowest average rating (4.1). The most desirable degree of tenderness might have been exceeded with the addition of the higher levels of soy protein. In some instances the patties became too crumbly and though evaluated as being tender would be rated lower in acceptability.

These data suggest that cooking losses differed between patties, since all-beef patties were observed to shrink more than patties containing soy additives. Judge et al. (1974) reported that shrinkage in patties was substantially reduced by soy additives. The effect of soy additives on cooking losses was also reported by Kotula and Rough (1975) and Drake et al. (1975).

Overall acceptability. All-beef patties and patties with textured soy protein usually were rated significantly higher ($P < 0.05$) than patties with concentrates (Table 6). On the average, patties with 30% soy protein were scored lower than the corresponding patty with 20% soy protein, but the differences were not always significant ($P < 0.05$). Though some panelists were able to detect old condition rancidity in beef patties after 9 and 12 months storage, the all-beef patties were rated about as good as, or better than the other patties tested.

The effect of storage on organoleptic quality. Average tri-monthly scores for palatability traits are summarized in Table 7. None of the traits rated decreased in score. This supports chemical data which demonstrated no important chemical decomposition during the year of storage. Although TBA values steadily increased with storage, only a few panelists

could detect rancidity in the cooked patties. Six panelists reported on old or rancid flavor in patties stored 12 months. A few panelists evaluating the patties after 9 months commented that the patties had exceeded their shelf life. Scores for some traits increased during storage.

Organoleptic evaluation — 13-member panel

Effects of condiments on palatability traits of patties are presented in Table 8. Scores for flavor, aroma, tenderness and overall acceptability were significantly higher for patties served with condiments than patties served without. Differences in appearance were not significant ($P < 0.05$). Scores for juiciness were somewhat lower for patties served with condiments, possibly because the bun absorbed the juices.

Chemical analyses of soy proteins

The chemical composition of the soy protein products (Table 9) was similar to that reported by Batchner et al. (1971). However, ash, crude fiber, fat and protein appear higher because these values are reported on a moisture free basis. If reported on a moisture present basis the percent protein for products A through F would be 53.82, 49.47, 49.90, 52.16, 65.10, and 64.52 respectively.

Chemical analyses of fabricated patties

Fabricated patties were analyzed tri-monthly to ensure that patties evaluated for palatability and acceptance by the panels were substantially the same in proximate composition throughout the evaluation periods. The analyses also provide input into the nutritional data bank.

Ash. Patties containing concentrated soy protein and all-beef patties generally had lower ash contents than patties containing textured soy products (Table 10). Ash content was higher in patties with 30% soy protein than in those with 20%. This simply reflected the increase in soy protein, which had a higher concentration of ash than the beef which the protein

replaced. Based on data collected over all months, ash content ranged from 0.86% (F-20%) to 1.39% (A-30%), and probably had no effect on palatability traits.

Fat. During fabrication of patties, an attempt was made to maintain fat content relatively constant at 20.5% in all patties. However, on analyses of patties (Table 10) fat content over all months ranged from 18.37% (F-30%) to 23.41% (E-20%). These variations were attributed to differences between and within lots of beef used in formulation of the patties. More precise control of fat content in the patties was not possible under the commercial conditions used in the study. We did not analyze each patty served to the panelists, therefore, we cannot indicate with certainty that the magnitude of the fat content fluctuations did not affect palatability traits.

Moisture. Patties containing soy concentrates had a higher average content of moisture than the patties with textured soy (Table 10). This was expected because large volumes of water were used to hydrate the concentrates in accordance with normal usage. Moisture content over all months ranged from 54.77% (B-30%) to 61.41% (F-30%).

Protein. Protein content (Table 10) was relatively constant over all patties and ranged from 16.70% (C-30%) to 18.05% (all-beef).

pH. The patties containing 20 or 30% soy protein in general had a slightly higher pH than the all-beef or the patties from Brand F-Soy (Table 10). However, even when these differences were significant, the magnitude of the difference was of no immediate importance. The minimum value was 5.52 (F-30%); the maximum value, 6.25 (B-30%). Except for product F, all patties containing soy protein had a higher pH than the all-beef patties.

TBA number. Concentrations of malonaldehyde, as an index of rancidity in the patties, are shown in Table 11. The highest initial value was recorded for all-beef patties followed by product F-30% and 20%; the lowest was 0.5 for B-30%. Values for all months ranged from 0.47 to 5.47 (mg malonaldehyde/100-g sample). Differences in TBA number could not be explained by classification of data into textured and concentrates, or 20% and 30%.

Lecithin, a long established antioxidant, is often added

after fat extraction in the fabrication of soy protein and may be a major factor in differences in fat stability between products. Furthermore, variations in manufacturing procedures might affect the stability of the natural lecithin present in the soy product. Stevens et al. (1970) suggested that in soybeans, lipoygenase catalyzes oxidation, by molecular oxygen, of *cis*-methylene interrupted unsaturated fatty acids and their esters to respective hydroperoxides. Maga and Johnson (1972) reported 40% less polyunsaturated fatty acids in soybean milk prepared by cold, than by hot extraction procedures. Fujimaki and co-workers (1966) stated that the following chemical and physical factors can accelerate lipid degradation in soy protein during fabrication: decomposition of natural antioxidants; content of metal catalysts; increased surface area, atmospheric oxygen, and humidity. Sessa et al. (1969) concluded that some lipid degradation occurred in the preparation of defatted flakes and, more importantly, that characteristic soybean off-flavors were closely associated with certain lipids and their decomposition products. Bowers and Engler (1975) also reported some antioxidant effects of soy.

Peroxide value. Peroxide values of the patties are shown in Table 12. Over all months the highest peroxide value was 11.79 meq/kg sample (F-30%), while the lowest was 0.844 (D-30%). Peroxide content was greatest in all-beef patties and F-30% as in the TBA analysis. The correlation between overall TBA and peroxide values was $R = 0.46$ and a coefficient of determination of $r^2 = 0.21$, indicating a rather poor relationship between the two procedures.

Recently, use of tests for peroxides has been limited due to the strictly empirical nature of the methodology. Furthermore, the literature reports that although peroxide number may indicate lipid quality in early stages of deterioration; it becomes less reliable as oxidation proceeds because of degradation of peroxides into many secondary products, including aldehydes, ketones, alcohols and hydrocarbons. The glyceride structure of the lipid also affects the peroxide value during oxidation. Triglycerides, such as those found in soybeans, contain large quantities of polyunsaturated fatty acids (linoleic and linolenic) and have high initial peroxide contents. In our tests the color change during titrations was not distinct,

making determinations rather difficult. Although this information certainly places considerable doubt on the data as being an actual representation of peroxide content and extent of lipid oxidation, it was noted that the higher values for peroxide were obtained on all-beef and F-30% patties as was the case for the TBA test. Rackis et al. (1972) reported the presence of peroxidases in maturing soybeans, but these have not been investigated in relation to their effect on soy protein products.

Effect of box location on variables studied

Average values for ash, fat, moisture, protein, pH, TBA and peroxide value of samples taken from the tops and bottoms of boxes, for all months of storage were determined. Only the 6-month values showed any significant difference (moisture, TBA) between box location. However, combined analyses over all months indicated samples from the top had significantly less moisture content and significantly higher TBA and peroxide values when compared to corresponding patties from the bottom of the boxes. The magnitude of these differences, however, was too small to be of consequence.

CONCLUSIONS

A CONSUMER PANEL did differentiate between patties containing textured soy protein or concentrate when compared to all meat patties. Patties containing 20% textured soy protein were rated about equal to all-beef patties. Patties containing soy concentrate at either 20% or 30% or patties with textured soy protein at 30% were less desirable than the all-beef patties. Brand differences were evident among the textured soy protein and also between the soy concentrate. When patties containing soy were served to a panel with condiments, acceptability increased. Thus, some brands of textured soy protein can be added at the 20% level as an adjunct to ground meat without detection or adverse reaction by consumers.

The development of rancidity during 12-month storage at 0°C, as measured by the TBA test, was less for patties containing soy protein than for the all-beef patties. The Armed Forces and others requiring a 9-month frozen shelf life can thus take advantage of the benefit of adding soy protein to beef patties without experiencing an inordinate rate of rancidity development.

USE OF MECHANICALLY DEBONED MEAT IN GROUND BEEF PATTIES

ABSTRACT

Palatability of cooked patties from seven formulations of ground beef patties containing 0–30% of added mechanically deboned beef was characterized. Frozen patties were broiled 9 min on an electric grill at 230°C to a "medium" degree of doneness and served to a 7-member trained panel. Mean panel ratings for overall acceptability were greater for patties containing 5, 10, 15 and 20% MDB than for the control (0% MDB). Patties containing 25 and 30% MDB had significantly lower flavor and acceptability ratings than control. As the percentages of added MDB increased, panel ratings for tenderness and juiciness increased. The amount of detectable connective tissue decreased significantly as the percentage of added MDB increased.

INTRODUCTION

THE USDA MPI Bull. 865 (USDA, 1974), providing for the preparation, labeling and distribution of mechanically deboned red meat, has provided means for the possible use of large amounts of protein previously not recovered as a food-grade product. It is estimated that 737 million pounds of beef, 374 million pounds of pork and 19 million pounds of lamb and mutton could become available for human consumption each year by use of this process (Pietraszek, 1975). The technology of production and the characterization of mechanically deboned meats have been studied by Field et al. (1974a, b, c); Field and Riley (1974) and Field (1974). Mechanically deboned meats may be produced from whole carcasses or from the partially cleaned bones from a hand boning operation.

A recent proposal by the U.S. Department of Agriculture (USDA, 1976) stipulated certain requirements for the use of mechanically deboned meat. This proposal would not allow mechanically deboned meat to be used in ground beef, chopped beef or hamburger but would allow it in beef patties. The feasibility of using mechanically deboned meat in ground beef patties has not been studied in detail. The effects of mechanically deboned meat on the sensory properties, storage stability, and composition of ground beef patties have not been documented. The objective of this study was to evaluate the effects of various levels of mechanically deboned meat on palatability and cooking properties of ground beef patties.

EXPERIMENTAL

Meat formulations

The seven formulations of ground beef that were tested are defined in Table 1. Raw meat materials were obtained from U.S. Utility triangles (chuck, foreshank, brisket and plate) and U.S. Choice plates that were fabricated for the AA USDA school lunch program under the supervision of a USDA meat grader (USDA, 1973). Coarse ground samples were randomly selected throughout the daily production (150,000 lb) until a sufficient quantity for the formulations was obtained.

All hand boned meat was ground through a 1.90 cm plate with a Weiler grinder. Mechanically deboned beef (MDB) was obtained from a mixture of necks, backs, ribs and pelvic girdle of U.S. Utility grade beef carcasses that had been manually boned. These bones were passed through a bone cutter into a model AU 4171 Beehive boning machine equipped with a cylinder having 0.46 mm diameter holes. Deboned meat was boxed, quick frozen and stored at -34°C for subsequent

analysis and product formulation. Prior to formulation, the frozen MDB was ground through a 1.90 cm plate with a Weiler grinder and stored at -30°C.

For each formulation, appropriate amounts of coarse ground beef and MDB were mixed for 3–4 min in a Chemetron mixer. During mixing, CO₂ snow was injected twice in order to maintain an internal temperature of 7°C or less. Following mixing, three random samples were taken for fat analysis with the Hobart fat testing apparatus. Additional fat or lean from U.S. Choice plates was mixed into the formulation to adjust the fat content to about 23%.

The individual batches were ground through a 0.32 cm plate with a Weiler grinder. One hundred patties (114g in weight and 0.95 cm thick) per formulation were formed with a Hollmatic Model 500 patty machine. During processing the product's internal temperature did not exceed 7°C. The remaining product from each treatment was stuffed into 0.90 kg "Keeper Casings" via a VeMag Pump (Model 43). The 0.90 kg packages and patties were boxed separately and placed in a -45°C blast freezer for 48 hr and subsequently stored at -30°C until shipment from Miami, FL to Beltsville, MD.

Chemical analysis

The MDB and five patties from each formulation were analyzed for calcium by atomic absorption spectrophotometry as outlined by Perkin-Elmer Corp. (1964). Essential amino acids were determined, as percent of total protein (except hydroxyproline, tryptophan and hydroxyllysine) by use of the Beckman Modified 121 Amino Acid Analyzer. Protein efficiency ratio (PER) was calculated according to procedures outlined by Alsmeyer et al. (1974). Patties for uncooked fat and moisture analysis were frozen in liquid nitrogen and powdered in a high speed blender. Moisture was determined as the mean weight loss of duplicate 3g samples after drying for 24 hr at 102°C. Fat content was determined as the weight loss of the dried samples after extraction for 16 hr in a Soxhlet apparatus with 35 ml of diethyl ether. The heaters were adjusted to allow 3–4 drops of ether per second to drip through the sample.

Objective evaluations

Frozen patties were broiled 9 min (4.5 min on each side) on an electric grill (approximately 275°C) to a "medium" degree of doneness. Ten patties from each formulation were randomly selected, cooked, and weighed immediately after cooking to determine weight loss during cooking. Values are reported as loss from the frozen to the cooked state. Degree of doneness was scored by a two-member panel with the use of an 8-point standardized photographic scale 5 min after sectioning. The same ten patties were evaluated with the Instron Universal Testing Instrument for maximum shear force by use of the single blade technique as described by Cross et al. (1976a).

Table 1—Proportion of mechanically deboned beef (MDB) in the ground beef formulation

% MDB	Beef ^a kg	MDB kg	Total ^b kg
0	184.0	0	184.0
5	87.4	4.4	91.8
10	165.6	16.6	182.2
15	78.2	11.8	90.0
20	147.2	29.4	176.6
25	69.0	17.3	86.3
30	120.8	30.0	150.8

Trained sensory panel evaluation

Male and female panelists were selected from the scientific and ancillary staff of the Agricultural Research Center. Selection was based on assessments of repeatability of scores on duplicate samples and consistency of ratings in relation to the group. Training was conducted over a period of 3 wk and data from the training sessions provided information for selection of a 7-member panel. After each training session, discussions were held with the panelists in order to achieve unanimity in the interpretation of the scoring system. Panelists evaluated the hot samples (approx 20–25g) in booths equipped with MacBeth "North Sky Daylight" lighting. The trained 7-member panel rated each patty for tenderness and juiciness on an 8-point rating scale (8 = extremely tender or juicy and 1 = extremely tough or dry). The amount of connective tissue residue remaining at the end of mastication was rated on an 8-point scale (8 = none and 1 = abundant amount). The panel was trained to evaluate tenderness, juiciness and amount of connective tissue. The panel was also asked to subjectively rate the samples for desirability of appearance, aroma, flavor and for overall desirability (8 = extremely desirable and 1 = extremely undesirable). The taste panel evaluation was conducted over a time span of 4 wk with a total of 14 sessions with four samples per session. Each of the four samples were sampled individually and the order of presentation randomized. Each treatment (Table 1) was repeated eight times over the 14 sessions.

Consumer panel evaluation

Fifty patties from each formulation were shipped by air freight to meat scientists at Texas A & M University for consumer panel evaluation. Frozen patties were broiled 14 min (7 min on each side) on an electric grill to a "medium" degree of doneness. Cooking times varied for patties prepared at the two locations because the grills used at the Texas A & M laboratory were wrapped with foil to control the flow of air during cooking. Thus, the cooking time required to reach the same degree of doneness was longer. During the course of 1 wk, 77 consumer panelists (age range 19–53; 68 males and 9 females) were asked to evaluate ground beef patties formulated with different amounts of mechanically deboned beef. Each panelist was asked to evaluate samples from four of the seven treatments using an incomplete latin square design. Panelists were familiarized with the taste panel forms, but were not told the composition of the beef patties. Each panelist scored the sample for appearance, flavor, texture, juiciness and overall desirability on a like/dislike scale, with 3 = like extremely and 1 = dislike extremely. The panelists were also asked to classify the texture and flavor as acceptable or unacceptable and to check one or more blanks corresponding to any off-texture or flavor.

Statistical analysis

Data were reduced by analysis of variance as outlined by Steel and Torrie (1960). When treatments (percent deboned meat) were found to be significant, the relationship between percent deboned meat and the trained sensory response was studied by fitting a response function to the data rather than using mean separation. When treatments are equally spaced values of a theoretically continuous variable such as percent deboned meat, the single comparisons given by mean separation may not give the most information about the problem being studied. In this study the more important task was to find if there were possibly some

Table 3 — Mean values for cooking loss, degree of doneness and shear force

continuous relationship between percent of deboned meat and palatability — perhaps to be approximated by a polynomial function. If a relationship exists, the order of the polynomial which approximates it needs to be determined. These questions are not addressed using any classical mean separation techniques, but rather are addressed using single degree of freedom contrasts or orthogonal polynomials in the analysis of variance. Since, in this study, percent deboned meat is a continuous variable, the more approximate question of a functional relationship between percent deboned meat and palatability characteristic was investigated. Polynomials of appropriate order are reported.

RESULTS & DISCUSSION

RESULTS OF COMPOSITION of uncooked ground beef patties containing different levels of mechanically deboned beef (MDB) are presented in Table 2. As expected, moisture content increased as fat content decreased. Percent calcium increased with level of MDB in the formulation. The 100% MDB sample contained 0.74% calcium which is within the level in the USDA proposed regulations (USDA, 1976). The maximum percentage of calcium in the ground beef mixtures was 0.19% in the 30% MDB formulation. PER and percentage of essential amino acids exceeded the proposed USDA requirements (USDA, 1976) in all formulations. The addition of MDB to ground beef enhanced the nutritional quality of the product by increasing the levels of calcium, PER and essential amino acids. Forbes et al. (1921), Mitchell et al. (1937) and Walker (1972) reported that calcium from bone is readily absorbed. The additional calcium in MDB may be nutritionally beneficial since many of the 138 articles reviewed by Walker (1972) point to calcium deficiencies in the human diet.

Mean values for cooking loss, degree of doneness and Instron shear force are presented in Table 3. Levels of MDB and cooking losses were not consistently associated. The formulation with the highest moisture content (20% MDB, Table 2) also sustained the highest cooking loss; although the cooking loss was not significantly different from the control formulation. Degree of doneness ratings increased (less well done) with level of MDB. Apparently cooking times might require slight adjustments if MDB were added. Maximum force required to shear a beef patty decreased significantly with increased levels of MDB. However, the formulation with 5% added MDB was not significantly different in shear force from the control formulation.

Tenderness and juiciness increased and amount of connective tissue (subjectively evaluated by panel) decreased with increased amounts of MDB (Table 4). The control formulation was made up of Utility triangles and Choice plates. Cross et al. (1976b) reported that ground beef prepared from U.S. Utility or lower grade beef was unacceptably tough and high in de-

Table 4 — Trained descriptive panel palatability ratings of ground beef patties containing mechanically deboned beef.

Treatment	Tenderness ^a	Juiciness ^b	Connective tissue ^c	Appearance ^d	Aroma ^d	Flavor ^d	Overall ^d
Control, 0% MDB	5.2	5.9	4.7	6.0	6.0	6.1	5.6
5% MDB	5.7	5.9	5.3	6.2	6.0	6.2	6.0

^a Tenderness: 8 = extremely tender and 1 = extremely tough.

^b Juiciness: 8 = extremely juicy and 1 = extremely dry.

^c Connective tissue: 8 = none and 1 = abundant

^d Appearance, aroma, flavor and overall: 8 = extremely desirable and 1 = extremely undesirable.

* No significant linear or quadratic effects or pairwise differences found among means

detectable connective tissue. In the present study, MDB apparently minimized the undesirable textural properties of Utility grade ground beef. The mechanism is unknown, but possibly MDB diluted the strands of connective tissue in the formulation so that its detection was minimized. Field et al. (1974a, b, c) and Field et al. (1976) reported that mechanically deboned meat is always lower in connective tissue than hand boned meat because some tendon is discarded with the bone.

Appearance and aroma ratings were not affected significantly ($P < 0.05$) by addition of MDB in the formulation (Table 4). The appearance ratings increased slightly as the level of MDB increased, probably because of the darker brown surface and the "medium rare" degree of doneness.

Flavor seems to be the limiting factor in adding MDB to ground beef (Table 4). Except for the 5% MDB formulation, flavor ratings decreased with added MDB. The decrease was greatest between the 20 and 25% levels. A sensory parameter rating of 5.0 or above is usually considered "acceptable," while 4.9 and below is considered "unacceptable." These are somewhat arbitrary designations and therefore should not be applied rigidly. Apparently MDB can be added at least to the 15 or 20% level without approaching this 5.0/4.9 cutoff. Ratings for overall acceptability were usually closely aligned with the one or two limiting (or lowest) palatability traits.

The means in Table 4 suggested that the seven sensory parameters were strongly related to the percent MDB. Therefore, as previously discussed in the experimental section, rather than perform mean separation on the data in Table 4, a polynomial in terms of percent MDB was fit to the means for selected taste panel traits and was corrected for other effects in the study (Table 5).

The functions show that ratings for tenderness, juiciness and amount of connective tissue increased linearly with percent MDB. For overall acceptability, the response initially increased then decreased as MDB increased. The maximum estimated response for overall acceptability (5.87) occurred at the 7.4% MDB level. The function for flavor has the same form as that for overall; however, the estimated maximum response was at 0.1% MDB which indicates essentially that flavor decreased as MDB increased.

Consumer panel evaluations

All means for consumer palatability ratings were above 5.0 (Table 6), and did not differ significantly among formulations for appearance, flavor and overall acceptability. Trends are similar for the trained (Table 4) and the consumer panels (Table 6); texture or tenderness and juiciness tended to increase with added MDB. The failure of the consumer panel to detect significant differences between the control patties and patties with MDB might be explained by the fact that the consumer panel sampled the products from each treatment only once, while the trained panel sampled each product eight times. Pos-

sibly the consumer panel would have begun to detect differences with prolonged testing or training. The trained panelists were selected on the basis of their ability to detect differences in the test attributes and probably were more sensitive to differences than the untrained consumers.

The consumer panel also rated texture and flavor as either "acceptable" or "unacceptable" (Tables 7 and 8). Each panelist was asked to classify the texture or flavor of the "unacceptable" patties by checking one or more blanks corresponding to any off flavor or texture. Except for the 25 and 30% levels, the percent rated as "unacceptable" in texture (Table 7) decreased with added MDB. More than 60% of the panelists rated the control patties as "unacceptable" in texture. The predominant defect was described as "too tough or rubbery" followed

^a Numerical values are percentages of responses.^b Numerical values are percentages of responses assigned by panelists who considered the flavor unacceptable. n = 77 panelists.

by "too coarse." Consumer panelists rated patties with high levels of MDB as being "too mushy" or "too fine." Apparently the addition of MDB at levels up to 15 or 20% tended to offset the undesirable textural characteristics of the control beef patties.

The percentage of patties rated as "unacceptable" in flavor increased with the higher levels of MDB (Table 8). More than 40% of the panelists rated patties as "acceptable" in flavor. Apparently, the flavor of patties was acceptable to more panelists than was the texture (Table 7). The predominant defect in all treatment groups was described as "musty." Further research, with a trained flavor profile panel, should be conducted to identify the intensity and order of appearance of the flavor components.

It was concluded, from the palatability and cooking loss data, that MDB can be added to ground beef at levels up to 15 or 20%. The textural properties of the cooked beef patty were improved by the addition of MDB. These conclusions are supported by data from trained and consumer panels. The protein quality of ground beef was enhanced by the addition of MDB as evidenced by increased PER and percent essential amino acids. The increased levels of calcium may also improve the nutritional value of the beef patties as explained by Forbes et al. (1921); Mitchell et al. (1937) and Walker (1972). Of the factors studied, undesirable flavor and mushy texture were the most common objections expressed by panelists about ground beef patties that contained high levels of MDB. Flavor of MDB should be monitored during prolonged storage at different temperatures to further define possible limitations on the use of MDB in ground beef patty formulations.

EFFECT OF DESINEWING VERSUS GRINDING ON TEXTURAL PROPERTIES OF BEEF

H. R. CROSS, B. W. BERRY, J. E. NICHOLS, R. S. ELDER and J. A. QUICK

ABSTRACT

The objective of this study was to evaluate the effect of mechanical desinewing (a new process whereby the major portion of the sinew or connective tissue and foreign particles is removed) vs grinding on textural properties of comminuted beef. Desinewing generally improved textural properties of beef patties with greatest effects on meat from mature animals. The 0.19 cm desinewing head was superior to 0.25 or 0.32, but further research is needed to refine head selection.

INTRODUCTION

IN THE UNITED STATES the consumption of ground beef has increased steadily over the past decade. Cross et al. (1976a, 1977) reported that connective tissue was and is a major problem associated with the acceptance of ground beef. They found that meat from U.S. Utility or lower quality or from minor cuts of any grade, produced a ground product that was unacceptably high in connective tissue. Cross et al. (1976b) reported that method of grinding affected textural properties of ground beef, especially the amount of connective tissue remaining in the cooked product. These results indicated that the size of the plates in the initial grind were directly related to the amount of connective tissue in the cooked product. The major sources of lean for ground beef are minor cut trimmings from young cattle and major cuts from older, lower quality cattle. Since it is not economically feasible for the industry to alter its source of lean, we are investigating methods of comminution that would remove a portion of the objectionable connective tissue.

A new process has been developed whereby the major portion of the sinew or connective tissue and foreign particles can be removed. The process is called "desinewing" and the device is an adaptation of the Beehive mechanical deboning machine. Gillett and Tanatikarnjatthep (1976) reported that mechanical desinewing removed about half of the connective tissue from beef shanks and plates. The objective of this study was to evaluate the effect of desinewing versus grinding on textural properties of comminuted beef.

EXPERIMENTAL

EIGHTEEN FORMULATIONS of comminuted beef were prepared as outlined in Table 1. All raw materials were selected from the same day's slaughter. The various cuts were removed from each carcass, boned and shipped about 10 miles in a refrigerated truck to the commercial research laboratory. The plates and flanks from the U.S. Choice minor cuts were partially trimmed of fat prior to comminution. About 40% of the Choice minor cuts consisted of undefatted foreshank lean and fat. Fat from U.S. Choice plates was added to the bull triangle and U.S. Utility triangle meat to increase the fat content.

For each treatment, a minimum batch of 50 kg was prepared. All raw material was passed through a grinder plate having 5.08 cm diameter holes. Grab samples were collected for fat analysis, and were further comminuted by passing them through a colloid mill. Fat content was determined by the Modified Babcock procedure. Fat content was standardized at $24 \pm 2\%$ by the addition of appropriate amounts of fat or lean. Based on previous determinations, the desinewing process was expected to remove 2–3% of the fat; therefore, the fat content for the raw materials to be desinewed was adjusted to about 26%.

Authors Cross, Berry, Nichols and Quick are with the Meat Science Research Laboratory, FR, USDA, Beltsville, MD 20705. Author Elder is with the AMS, USDA, Washington, DC.

^a CM = flanks, plates and foreshanks; UT and BT = plates, foreshanks and chucks; G = Three stage grind, 5.08, 1.90 and 0.32 cm plates; D1 = 0.19 cm head; D2 = 0.25 cm head; and D3 = 0.32 cm head

Grinding

Following the initial grind and fat adjustment the meat was mixed for 2 min in a mechanical mixer. Temperature was monitored during the mixing process and if it exceeded 2–3°C, sufficient CO₂ snow was added to bring the internal temperature of the ground product below 3°C. After mixing, the product was ground through a 1.90 cm plate and finally through a 0.32 cm plate.

Desinewing

Meat was passed through a Beehive Desinewing Machine (Model AU 6173). Heads of three different sizes were used and had holes with diameters of 0.19, 0.25 and 0.32 cm. Prior to the desinewing, fat content was adjusted by the addition of fat that had been passed through the 0.19 cm desinewing head. The product was mixed for 2 min and CO₂ snow was added if necessary.

Combinations

Various combinations of raw meat materials (U.S. Choice minor cuts and U.S. Utility triangles) and methods of comminution (grind and desinew) were prepared. Desinewed meat (0.19 cm head) was added in equal amounts to ground meat after it had been passed through the 1.90 cm plate. Following a 2-min mix, the product was ground through the 0.32 cm grinder plate. Desinewed Utility triangles and Choice minor cuts were combined in equal amounts and mixed for 2 min but were not ground.

Patties

Comminuted meat from each treatment was formed into 142g patties with a Hollymatic Patty Machine. Patties were placed in plastic bags, covered with CO₂ snow and placed in a –20°C freezer. After 72 hr, patties were packed in dry ice and shipped via air freight to Beltsville, MD.

Cooking

Patties were broiled from the frozen state on electric Farberware grills (model 450) for 6 min per side. Cooked patties were quartered and served immediately to panelists for sensory evaluation. Degree of

^b Desinewing methods differed according to diameter of holes in the heads of the machine.

doneness was evaluated, by comparison with color photographs, on all cooked patties 5 min after cooking.

Panel selection and training

A 10-member panel was selected and trained in descriptive attributes by the procedures of Cross et al. (1978). The panel rated the following attributes on an 8-point structured scale: (a) tenderness and juiciness, with 8 = extremely tender and juicy; and 1 = extremely tough and dry; and (b) connective tissue amount with 8 = none and 1 = abundant. Panelists rated five samples at each of 22 sessions. Each treatment was replicated six times and samples to be evaluated in each session were selected via a table of random numbers.

Instron shear

Ten patties from each treatment were broiled for determination of shear values. The cooked patties were cooled for at least 2 hr, and shear force was measured on each quarter of the patty with the single blade shearing device attached to the Instron as described by Cross et al. (1976b). Data were recorded for the maximum force required to shear through the meat patty.

Hydroxyproline

Duplicate samples (4g) of frozen powdered meat from each treatment were heated for 70 min at 77°C in 0.25% strength Ringer's solution and separated into supernatant and residue fractions according to the procedures of Hill (1966). Each fraction was individually hydrolyzed in 6N HCl at 102°C for 16 hr at 1 atm pressure.

The hydroxyproline content was determined as outlined by Bergman and Loxley (1961). Total collagen content (mg/g) was calculated by multiplying the hydroxyproline content of the residue by 7.25 and that of the supernatant by 7.52.

Statistical analysis

The experimental design was structured so that each treatment occurred once in each replication and once in each order (1 to 5). The design was a partially balanced incomplete block design according to Clatworthy (1973). Each observation used in the analysis was the average of the scores of all panelists. Data were subjected to statistical analysis of variance according to Snedecor (1956) and to mean separation by Scheffe's method (1959). Means for the taste panel traits were adjusted for session/replication effects. Means for degree of doneness were evaluated by nonparametric analysis of variance (Kruskal-Wallis procedure) discussed in Hollander and Wolfe (1973).

RESULTS & DISCUSSION

DATA IN TABLE 2 describe the effect of desinewing method

on textural and chemical properties of beef. Since interactions between type or grade of meat and method of comminution were significant, the data are presented separately for each type and grade of meat. Three desinewing methods (0.19, 0.25 and 0.32 cm hole sizes) were applied to Choice minor cuts (CM) and Utility triangles (UT). No significant differences among methods were evident for CM cuts in either panel or Instron ratings (Table 2). For UT, the methods with the 0.19 and 0.25 cm head sizes were superior in terms of panel ratings of tenderness, and the 0.19 cm head was best for connective tissue amount and Instron shear force.

Degree of doneness, cooking losses, and juiciness were not significantly affected by method of desinewing (data not shown). As the hole size increased from 0.19 to 0.25 and 0.32 cm, the amount of total collagen in the final product increased significantly. With CM or UT, the amount of collagen in the product was significantly less from the 0.19 than the 0.32 cm head. These differences in collagen were also reflected by the differences in the panelists' ratings for tenderness and connective tissue.

Based on the results in Table 2, the desinewing method with the 0.19 cm head was used to prepare meat for comparison with ground meat. Data in Table 3 describe the effect of grinding or desinewing on the textural and chemical properties of beef. The two methods of comminution (grinding and desinewing—0.19 cm head) were applied to Choice minor cuts (CM), Utility triangles (UT), Choice flanks (CF) and bull triangles (BT). Bull triangles were from 'C' maturity carcasses and UT from D/E maturity carcasses. Although not all differences were significant, desinewed patties from CM cuts consistently tended to be rated more tender (panel and Instron) and lower in detectable connective tissue than ground patties (Table 4). Patties from desinewed UT and BT cuts were rated significantly more tender (panel) and lower in connective tissue than patties from ground UT and BT. Patties from desinewed BT were also more tender, as indicated by lower Instron values, than patties from ground BT. Desinewed UT patties also had significantly higher juiciness ratings than ground patties (not shown in table).

Apparently, the effect of desinewing was greatest on cuts from older (C-E versus A maturity) carcasses, which usually

^b Desinewed beef was passed through the 0.19 cm head.

have large amounts of tough connective tissue. This is important because mature animals are the major source of beef for hamburger. Cross et al. (1976a, 1977) indicated that ground beef from old animals is unacceptably high in connective tissue. The panel rated patties made from ground BT lowest in quality in terms of tenderness and connective tissue, but rated those from desinewed BT highest for these same traits (Table 3).

The effects of desinewing versus grinding on total cooking loss and degree of doneness were not significant (data not shown). From all cuts except CF, desinewed beef contained significantly less collagen than ground beef. These differences were reflected in the ratings for tenderness and connective tissue (Table 3).

Three mixtures of desinewed and ground beef from two classes of cuts (CM and UT) were prepared as outlined in Table 4. Generally, as the percent desinewed meat of the CM formulation increased, ratings for tenderness increased and Instron shear force decreased. Although these differences were not significant, the trend is similar to that in Table 2. For UT, 100% desinewed beef was the best in terms of tenderness, connective tissue and Instron shear force. It is impossible to explain why UT containing 50% ground/desinewed beef were rated tougher than either of the other formulations. This segment of the experiment will be repeated to determine whether that effect was real. Juiciness, cooking losses, and degree of doneness ratings were not significantly affected by the amount of desinewed beef in the formulation (data not shown). As expected, total collagen decreased as the percentage of desinewed beef increased. The change was greatest between 100% and 50% desinewed.

Various combinations of desinewed and ground cuts were prepared and the results are presented in Table 5. From CM and UT cuts, four 50/50 mixtures in all combinations, were prepared of ground and desinewed meat. The CM ground/UT desinewed and CM desinewed/UT ground treatments were more tender, according to the Instron, than the CM ground/UT ground mixture. Juiciness, total cooking loss, and degree of doneness did not differ significantly among the four mixtures (data not shown). Mixtures containing UT desinewed beef contained significantly less total collagen than other mixtures. In mixtures with ground UT beef, desinewing of CM did

not significantly reduce total collagen. Generally, there appears to be few differences in tenderness between mixed ground beef regardless of the desinewing treatment.

CONCLUSIONS

DESINEWING generally improved the textural properties of beef patties. The effects of desinewing were greatest on meat from mature animals that were high in connective tissue. That finding is economically important because most ground beef is now prepared with meat from mature animals or with minor cuts from younger animals. Meat desinewed through the 0.19 cm head was superior to that desinewed through the 0.25 and 0.32 cm heads. Choice of the method of comminution probably should be based on the nature of the raw material, but further research is needed to refine the selection of heads.

OBJECTIVE MEASUREMENTS OF TEXTURE IN GROUND BEEF PATTIES

H. R. CROSS, MARILYN S. STANFIELD and W. J. FRANKS JR.

ABSTRACT

Beef patties were prepared from carcasses ranging in quality grade from U.S. Prime to Cutter and formulated into 16 grade/cut combinations. Texture was evaluated for each sample with three devices (two shear and one compression) adapted to the Instron Universal Testing Machine. The single blade shear (SBS) and circle blade shear (CBS) were used to determine the maximum force required to shear the sample and to measure the area under the curve, i.e., work. The maximum force required to compress a core to one-half its original thickness also was determined. In simple correlations, machine readings for single blade area under the curve and for maximum single blade shear force were the most highly correlated with the subjective panel evaluation of connective tissue amount (-0.93 and -0.92) and tenderness (-0.89 and -0.88). Correlations for CBS were highly significant but had lower coefficients (-0.86 , -0.78 ; -0.82 , -0.76 ; respectively) than the SBS. Regression equations containing single blade area, circle blade area and compression force accounted for 95.1% of the variability in subjective panel evaluations for amount of connective tissue and when circle blade shear replaced circle blade area, accounted for 92.6% of the variability in panel ratings for tenderness.

INTRODUCTION

RESEARCH on objective methods of measuring texture is not a new development. Lehman (1907) described two instruments for testing the tenderness of meat. Schultz (1957) summarized the advantages and disadvantages of various mechanical methods that had been used to measure meat tenderness. Voisey (1976) provides an excellent review of instruments used for meat tenderness evaluation. Interest continues in the development of new devices and the modification of existing devices, for the measurement of texture in meat (Szczeniak and Torgeson, 1965; Burrill et al., 1962; Sperring et al., 1959; Kelley et al., 1960; Spencer et al., 1962; Smith and Carpenter, 1973; Segars et al., 1975).

Tenderness is the principal attribute associated with texture in meats as evidenced by consumer preferences for tender meats. Of the many mechanical devices used to simulate or measure tenderness or texture as perceived by the sensory panel, the Warner-Bratzler instrument is probably the most popular (Szczeniak and Torgeson, 1965). That device is simple and inexpensive but generates data that may not always correlate highly with sensory tenderness. Szczeniak and Torgeson (1965) stated "that 41 of 51 research studies established good to highly significant relationships between Warner-Bratzler shear and sensory tenderness with the remaining studies showing poor to no significant correlations with sensory tenderness."

Many researchers have adapted the meat shear principle of the Warner-Bratzler apparatus to use with the Instron Universal Testing Machine. Because of its basic design and its capability to record force-distance relationships accurately, the Instron may be used to quantify other parameters of texture other than maximum shear force.

Few researchers have used instruments to evaluate texture

^a Combination consisted of chuck and plate in equal proportions

in ground beef. Cross et al. (1976) demonstrated sensory panel differences in texture (tenderness and amount of connective tissue) in ground beef formulated from different U.S. quality grades. We now report a secondary phase of that study. We evaluated three devices that were designed for use on the Instron to objectively measure texture in ground beef patties. The different U.S. quality grades and cut combinations provided ranges of tenderness, juiciness and connective tissue so that we could evaluate any possible relationships between mechanical measurements of texture and the sensory responses of a trained panel. We wanted to determine whether the mechanical devices could accurately evaluate, with respect to human evaluations, the textural characteristics of cooked ground beef patties.

EXPERIMENTAL

GROUND BEEF SAMPLES were prepared from 16 different grade/cut combinations (Table 1). Carcasses which were selected and fabricated as described by Cross et al. (1976), ranged in quality grade from U.S. Prime through U.S. Cutter to provide variation in texture. Fat content was standardized at $24 \pm 2\%$ by the addition of appropriate amounts of fat or lean and was determined with the Modified Babcock procedure. The ground meat was formed into 75-g patties which were 10 cm in diameter and 0.95 cm thick with a Holymatic Patty Machine. All patties were placed in boxes (4.5 kg to a box), frozen in a blast freezer (-30°C), and shipped from Oklahoma City, OK, to Beltsville, MD, via air freight.

Cooking

Patties were roasted from the frozen state in a 200°C oven for 9 min, quartered, and served as hot as possible to the panelists. Patties were allowed to cool for 60 min after cooking before sampling for shear and compression.

Panel selection and training

Male and female panelists were selected from the scientific and ancillary staff of the Agricultural Research Center, Beltsville, MD. Panelists were selected and trained according to the procedure outlined by Cross et al. (1978). Panelists individually evaluated the samples under red lights in booths.

The trained panel rated each patty for tenderness and juiciness on a

Fig. 1—Single blade shear.

Fig. 2—Circle blade shear.

9-point scale (9 = extremely tender or juicy and 1 = extremely tough or dry). Tenderness and juiciness were evaluated during the first 5–10 chews. The amount of connective tissue residue remaining at the end of mastication was rated on a 9-point scale (9 = none and 1 = very abundant amount). The taste panel evaluations were conducted over eight 3-day periods. Panelists evaluated six ground beef samples each day so that during each 3-day period all 16 grade/cut combinations were tested. In addition, two combinations were repeated once during each 3-day period. If each panelist had been present for every session, there would have been an equal number (9) of evaluations by each panelist on every ground beef combination. In the "ideal" panel situation each combination would have received 144 evaluations, but panelists' attendance was not perfect. Three panelists had fewer than 50 evaluations and averaged 120 evaluations out of a possible 144. To avoid problems in statistical analysis, created by a side disparity in the number of evaluations, we eliminated the data from these three members.

Mechanical measurements

Shear and compressive force tests were carried out with the Instron Universal Testing Machine (type TM). Two shear and one compression devices were adapted to the Instron machine. The rate of crosshead descent for all three tests was 25.54 cm per minute. All test cells were manufactured in-house. The single blade shear (SBS) device used in this study (Fig. 1) consisted of a rectangular dull-edged blade 6.00 cm wide and 0.11 cm thick. There was a 0.04 cm clearance between the shearing edge of the blade and the corresponding edge of the hole in the base plate where the shearing action occurred. Two cooked patties from each grade/cut combination were tested with the SBS. Each patty was cut into four equal sections (3.15 cm square \times 0.95 cm thick) to give eight samples per combination (Table 1).

The circle blade shear (CBS) device (Fig. 2) was similar to the slice tenderness evaluator (STE) described by Kulwich et al. (1963) and Segars et al. (1975), except that the CBS device did not have a mecha-

nism to puncture the sample prior to shear. The CBS device consisted of a flat plunger or coin shaped device, 2.52 cm in diameter and 0.72 cm thick, that sheared a sample placed over a cylindrical base. There was 0.01 cm clearance between the shearing edge of the device and the corresponding edge of the hole in the cylinder. Two cooked patties from each grade/cut combination were tested with the CBS. Each patty was cut into three cores (3.81 cm in diameter \times 0.95 cm thick) to give six samples per combination (Table 1). Data were recorded for maximum shear force (SBSHEAR and CBSHEAR) and for work or area under the peak curve (SBSAREA and CBSAREA).

The compression device consisted of a flat plate (9.68 cm \times 10.16 cm) and a pedestal-like device 7.62 cm in diameter and 0.65 cm thick (Fig. 3). A core (3.81 cm in diameter \times 0.95 cm thick) was placed on the plate and the force required to compress the cooked ground beef core to one-half its original thickness was measured. Eight cores were from each of two patties. Ten consecutive "strokes" or "chews," were made on each of the eight cores to give a total of 80 readings for each grade/cut combination (Table 1). Plots (not shown) of compression force (COMFORCE) versus stroke number (1–10) for each core within a combination were obtained. COMFORCE tended to steadily decrease from the first stroke through the tenth, with the rate of decrease becoming less with increasing stroke number. For any given combination, a relatively consistent difference existed between the COMFORCE plots of the eight cores. Examination of these plots indicated that for each stroke the average value of COMFORCE of the eight cores was meaningful in describing the relationships between COMFORCE and stroke number. For purposes of statistical analysis, we chose to average COMFORCE over all cores and strokes for each combination.

The overall average for sensory panel evaluations were used for each grade/cut combination, so there is one observation for each. The average for each combination was the best estimate of the "true" panel response. In this study, our primary interest was that "true," yet unknown, response. The rationale was similar for the use of the average machine reading to represent each combination.

Statistical analysis

Results of this study apply only to the average panel responses and to the average readings obtained from the Instron machine and do not necessarily represent evaluations by a single panelist or a single machine measurement. We used the stepwise regression procedure, described by Draper and Smith (1966), to select the best regression equations. We also investigated results from the forward selection and backward elimination regression procedures of Draper and Smith (1966). Those two procedures usually produced the same regression equations as the stepwise procedure. Instron readings were used as independent variables and sensory panel traits as dependent variables. The appropriate levels of significance were set at 5%. Regression analysis was used solely to indicate which combinations of Instron readings were meaningful in predicting sensory panel traits. We place no particular importance on the specific values of the partial regression coefficients and have not included them in our results and discussion.

RESULTS & DISCUSSION

CROSS ET AL. (1976) reported significant differences at the 5% level of significance between the 16 grade/cut combinations for panelist evaluations of tenderness, juiciness and connective tissue (Table 1). Results of analysis of variance (not shown) indicated that the means of the 16 combinations differed at the 5% level of significance, for each type of Instron measurement. Evaluation of the relationship between palatability characteristics and Instron readings begins with the simple correlation coefficients in Table 2. SBSAREA and SBSHEAR were most highly correlated with sensory panel scores for tenderness and connective tissue amount. The relationship between compression force and sensory panel traits was low and nonsignificant.

In the first set of regression analyses, all five Instron

Table 2—Simple correlation coefficients of the Instron readings and palatability characteristics

Instron	Palatability characteristics		
	Tenderness	Juiciness	Connective tissue
SBSHEAR ^a	-0.88**	-0.58*	-0.92**
SBSAREA ^a	-0.89**	-0.52*	-0.93**
CBSHEAR ^a	-0.76**	-0.56*	-0.78**
CBSAREA ^a	-0.82**	-0.47	-0.86**
COMFORCE ^a	-0.19	-0.14	-0.08

^a SBSHEAR = single blade shear; SBSAREA = single blade area; CBSHEAR = circle blade shear; CBSAREA = circle blade area; and COMFORCE = compression force.

* Significant at the $P < 0.05$ level.

** Significant at the $P < 0.01$ level.

Table 3—Overview of regression analyses with all five Instron readings as potential independent variables

Independent Instron	Dependent variables ^{a,b}		
	Tenderness	Juiciness	Connective tissue
SBSHEAR		X	
SBSAREA	X		X
CBSHEAR	X		
CBSAREA			X
COMFORCE	X		X
R ² (%)	92.6	33.2	95.7
S.E.E.	0.312	0.235	0.329

^a An "X" indicates the independent variables that were ultimately selected by the stepwise procedure when the appropriate levels of significance were set at 5%.

^b The overall sensory panel average evaluation and average Instron reading were used for each grade/cut combination. Consequently, there is one observation for each combination.

readings were considered as potential independent variables (Table 3). The Instron readings explained 92.6% and 95.7%, respectively, of the variability of tenderness and connective tissue amount. The low R^2 for juiciness apparently reflects the inability of the Instron shear and compressive force measurements to meaningfully correlate with sensory juiciness.

In stepwise regression analysis, the resulting equation is highly dependent upon the specific potential independent variables that are submitted for analysis. Any changes in the number and type of potential independent variables can result in different equations. Because of this situation, different sets of independent variables were used. Overviews of the results of these analyses for tenderness and connective tissue amount are provided in Tables 4 and 5, respectively.

In Tables 4 and 5 use of area readings in combination (SBSAREA and CBSAREA) usually gave slightly higher values of R^2 than use of shear readings (SBSHEAR and CBSHEAR)—equations 2 and 6 versus equations 1 and 5. The same situation existed when a third Instron variable (COMFORCE) was added—equation 4 versus equation 3 in Table 4—and the values of the R^2 's were not markedly increased.

For readings from either the single blade or the circle blade, either the area or shear values are meaningful alone, but not together. That finding is a direct result of the high correlation (not shown) between shear and area readings from the same device.

Some plots (not shown) of Instron readings versus palatability characteristics indicated that the relationship was slightly curvilinear and, therefore, suggested that the squares of those readings might improve the regression equations (data

Table 4—Overview of regression analyses for sensory panel tenderness

Eq	Independent variable ^{a,b}					R ² (%)	S.E.E.
	SBSHEAR	SBSAREA	CBSHEAR	CBSAREA	COMFORCE		
1	X		X			84.0	0.440
2		X		X		84.3	0.436
3	X		X		X	90.4	0.356
4		X		X	X	91.6	0.333

^a An "X" indicates the independent variables that were ultimately selected by the stepwise procedure when the levels of significance were set at 5%.

^b The overall sensory panel average evaluation and average Instron reading were used for each grade/cut combination. Consequently, there is one observation for each combination.

Table 5—Overview of regression analyses for sensory panel connective tissue

Eq	Independent variable ^{a,b}					R ² (%)	S.E.E.
	SBSHEAR	SBSAREA	CBSHEAR	CBSAREA	COMFORCE		
5	X		X			91.2	0.451
6		X		X		93.0	0.403
7		X		X	X	95.7	0.329

^a An "X" indicates the independent variables that were ultimately selected by the stepwise procedure when the levels of significance were set at 5%.

^b The overall sensory panel average evaluation and average Instron reading were used for each grade/cut combination. Consequently, there is one observation for each combination.

not presented). Squared terms were tested for the different regression procedures. Results of the regression analysis, however, indicated that the addition of squared machine readings as independent variables increased R^2 only slightly. We can, therefore, accept the basic machine readings as adequate for the regressions.

The shear force devices that we used for characterizing the texture of ground beef patties were acceptable and gave readings that were highly correlated with the sensory evaluation of patties. They were easy to use, allowed rapid testing of many samples and required relatively small samples. SBSAREA accounted for 79.2% and 86.5% of the variability in sensory panel tenderness and connective tissue amount, respectively (r^2 , Table 2). Regression equations for data from three Instron measurements from three different devices, accounted for 92.6% and 95.7% of the variability in tenderness and connective tissue amount, respectively (Table 3). The best two-variable, two-device equations accounted for 84.3% (#2—Table 4) and 93.0% (#6—Table 5) of the variability in tenderness and connective tissue amount, respectively.

The use of more than one device gave meaningful increases in R^2 with associated decreases in the standard error. Measurements of the area under the peak curves for shear forces, as measured by the circle and single blades, seemed to offer the best compromise between the use of only one device or the use of three different devices.
